THE Calendar of the Yorkshire College for the sixth session (1879–80) has just been published. It appears this year for the first time in stiff covers, and with the prospectus of the Leeds School of Medicine makes a book of 204 pages. The growth in the size of the calendar corresponds with the extension of the College curriculum, for several new classes are announced for the approaching session, which begins on October 7 next. Mr. W. Philp, M.A., B.Sc., has been appointed mathematical and classical tutor, and the College authorities have thus been able to arrange for a systematic oversight of students who are preparing for the examinations of the University of London. The Natural Philosophy lectures are now arranged in two courses. The first year's course comprises the requirements for London Matriculation, viz., Mechanics, Optics, and Heat; the second year courses, those for the B.A. and other degrees, viz., Mechanics, Heat, Acoustics, Light, Electricity, and Magnetism. The Chemistry Classes remain the same as last year. Students have the privilege of pursuing a course of practical chemistry in the laboratory at times convenient to themselves, and for such periods as they are able to devote to that study. The Saturday morning chemistry lecture and practical class are to be continued, schools and teachers having largely availed themselves of this opportunity in past sessions. The arrangements and the classes in Mathematics, Geology and Mining, Biology, Zoology and Comparative Anatomy, Botany, Civil and Mechanical Engineering, Latin, Greek, French, German, Oriental Languages, Coal Mining, and Textile Industries remain for the most part unaltered, but the important subject of Mental and Moral Science has been added, Logic being taken in the earlier part of the session, and Psychology in the later part. The classes in Modern Literature and History have been multiplied and rearranged, so as to give a complete course in Literature and History for the London Matriculation and 1st B.A. examinations, a complete course on the special subjects in Literature and History for the Cambridge Higher Local examination, and a course of History for the Cambridge Senior and Junior Local examinations, besides other classes for students not reading for examinations. The fees in some of these classes are fixed on a very low scale, to meet the requirements of teachers and others preparing for the University Local examination. This is an endeavour to extend the usefulness of the college, which will, no doubt, be warmly appreciated by the large class of persons directly affected by it. The department of Textile Industries continues to receive the attention it deserves, and although the students cannot be located in their new premises at Beech Grove at the opening of the Session, as had been hoped, their interests have been amply provided for in the temporary class rooms and in the weaving annexe in Cookridge Street. The practical value of the instruction given by Mr. Beaumont is widely recognised, and we observe that the committee are doing what they can to impress on the students in this department the value of a thorough acquaintance with the most important branches of textile manufacture. Arrangements for the establishment of a school of dyeing are in an advanced state. In the evening classes there are to be courses of lectures on Mechanics, Chemistry, Geology, Biology, Botany, and Engineering, and classes in Latin, Greek, English Grammar, and Textile Industries. A somewhat bold experiment is to be tried by the introduction of two short courses of lectures of a more popular character than the ordinary evening class lectures.

MR. T. JEFFERY PARKER, B.Sc., Demonstrator of Biology in the Royal School of Mines, has been appointed to the new lectureship on Biology at Bedford College, York Place, Portman Square.

THE City and Guilds of London Institute for the Advancement of Technical Education have issued a detailed programme of subjects in which examinations will be held in 1880. It embraces a great variety of subjects, in the more scientific of which some eminent men of science have been obtained as examiners. Any one interested in the matter will, no doubt, obtain a copy of the programme by applying to the Secretary, Mercers' Hall, E.C.

M. JULES FERRY has published a regulation tending to diminish the importance given to the *Compositions des Prix* in the several French educational establishments and to shorten the time assigned to the young competitors for writing their essays. Much dissatisfaction is felt by teachers and the best pupils at Government trying to repress the sense of emulation. It is expected that petitions will be sent to the French Parliament protesting against the supposed retrograde step taken by the Administration.

SCIENTIFIC SERIALS

Annalen der Physik und Chemie, No. 7.—In the opening paper, on electric limiting layers, Prof. Helmholtz studies the case where there is a difference of potential at the limiting surface of two different bodies, giving, along this surface, what he calls an "electric double layer," as, *e.g.*, when a zinc and a copper plate, in metallic connection, are approximated to each other. He groups together, in this relation, the phenomena of metallic electrodes in an undecomposed electrolyte, frictional electricity, flow of liquids on solids, and applies an explanation of the last-named case to various recorded phenomena of electrical action in liquids.—Herr Beetz describes a new investigation of the heat-conducting power of various liquids. The differences in this property, according as the temperatures were above or below 20°, are made manifest, and the discrepancies of previous data in part explained. The phenomena of heat conduction in liquids are considered to depend on mechanical molecular processes, or friction phenomena, as Kohlrausch has shown to be the case with electrolytic conduction.—A paper by Herr Barus treats of the thermo-electric position and electric conductivity of steel in its relation to hardening. He shows that the steel bars examined fell into two classes, those of the one class (the harder) being electro-negative to copper, those of the other (the softer) electro-positive. A simple method of classing steel is deduced from this. —In a second communication on experimental determination of

the velocity of light in crystals, Herr Kohlrausch finds that also for oblique sections of optically biaxial crystal Fresnel's theory of light-motion in crystals is fully in harmony with observation.—Remaining papers:—On elastic reaction in longitudinal extension, by Herr Neesen.—Researches on the elementary law of hydro-diffusion, by Herr H. F. Weber.—On the magnetic behaviour of pulverised iron, by Herr V. Waltenhofen.—On extra currents in conductors of various thickness, by Herr Herwig.

No. 8.—The transpiration of vapours is here the subject of a paper by Herr L. Meyer, whose method of experiment was to heat the substance under determinate regulated pressure to boiling, and let the vapour play over the capillary tube, and partly stream through into a vacuous cooled space, where it was condensed and after some time measured as liquid. Herr Meyer finds, *inter alia*, that the friction of vapour increases with rising temperature and faster than that of gases; further, the molecular volume in the vapour state, as in gases, seems to be greater at a low than at a high temperature.—In a lengthy (third) paper on the electric conduction of gases, Herr Hittorf describes many interesting effects obtained with a Bunsen battery of 1,600 elements. This gave him within wide limits, a constant glow discharge. He has no doubt that the character of phosphorescent light is to be attributed to the spectra of the first order. All non-metallic gases, whether elementary or compound, can probably be thrown into the phosphorescent state by the electric current giving such spectra. The electric behaviour of flame gases is different from that of the same gases at the same temperature, when not involved in the chemical process. In the glow-discharge, the author considers, there is not a transference of gas particles; and the propagation of the current everywhere (including the dark layers and space) is effected by a different process. The molecules of a gas have a real conductivity, like the particles of metals and electrolytes, inasmuch as they discharge in every direction the least difference of tension. The author supports, by experimental evidence, Faraday's views of the nature of discharge.—A peculiar spark discharge at the so-called negative pole of an induction apparatus is studied by Herr Hankel; there being a blunt point at the negative pole, and a plate or large ball at the positive, positive electricity may (by reason of oscillations in the coil), spring over from the point to the plate or ball in long sparks.—Remaining papers: Researches on the elementary law of hydro-diffusion (continued), by Herr H. F. Weber.—On the change of phase of light by reflection, by Herr Glan.—On the density of the luminous ether, by the same (the lower limiting value he assigns is 7,416 times that of Thomson).—The law of dispersion, by Herr Kettler.—The oxygen spectrum, by Dr. Schuster.—Generalisation of a theorem of attraction, by Herr Schalbach.—Contributions to a history of natural sciences among the Arabs, by Herr Wiedemann.

THE *Sitzungsberichte der königl. boehmischen Gesellschaft der Wissenschaften in Prag* (Jahrg. 1877 and 1878) contain the following papers of interest:—On the prehistoric vertebrate fauna of Bohemia, by Prof. Anton Fric.—On the recent history of botany, by Herr Ladislav Celakovsky.—On a new spectrometrical method, by Prof. K. V. Zenger.—On the bases of iconognosy, by Prof. F. Tilser.—On the gas-coal fauna of Zabor near Schlan, Kroucova near Renc, and Tremosna near Pilsen, and on the sphærosiderite balls of Zilov, by Dr. Anton Fric.—On the calculation of aplanatic katadioptric object glasses, by Prof. K. V. Zenger.—Several mathematical papers by Prof. Emil Weyr.—On some new microscopical and chemical methods for the determination of certain minerals, particularly of felspars, if they occur in very minute fragments or sections, and on the phenomena apparent in etched, natural, and ground surfaces of apatite, by Prof. Dr. Emanuel Boricky.—On the discovery of *Placoparia Zippei*, Corda, at the foot of the Lorenzi hill at Smichov near Prague, by Prof. Josef Korensky.—On the discovery of a tooth of *Hyæna spelæa* in the diluvial deposits of Hlubocerp.—Several mathematical papers by Prof. Franz Studnicka, Karl Zahradnik, and Josef Solin.—Critical remarks on Wigand's "Darwinismus" concerning the differences of Darwin's doctrine of descent and the "Genealogie der Urzellen," by Prof. Lad. Celakovsky.—On the distribution of vertebrates in ancient and recent geological periods, by Dr. Johann Palacky.—On species, forms, and hybrids of *Pilosella*, a subgenus of *Hieracium*, by Dr. Knaf.—On a new solar eye-piece and on a new position micrometer, by Prof. K. V. Zenger.—On the triple change of generation of plants, by Prof. Lad. Celakovsky.—On a new saurian from the limestone of the Permian formation of Braunau (Bohemia), by Prof. Anton Fric.—On the results of ombrometrical measurements made in Bohemia, particularly with reference to the meteorological net, by Prof. Fr. Studnicka.—On the international horticultural exhibition of Amsterdam, by Prof. Dr. M. Willkomm.—On a theorem of the potential theory, and on steel magnets, by Prof. A. von Waltenhofen.—On the south-eastern border of the European flora, by Dr. Johann Palacky.—A series of mathematical papers, by Franz Zrzavy, Gustav Schmidt, S. Günther, Wilhelm Matzka, Gust. Gruss, Gottlieb Becka, and S. Kantor.—New researches on compound fluorides by Prof. Fr. Stolba.—On the anatomy and systematics of *Enchytridæ*, by Dr. F. Vejdorsky.—On the porphyries of the Libcicer rock, by Prof. E. Boricky.—Analysis of the Moldau water, by Prof. A. Belohoubek.—On the theory of twin crystals, by Prof. J. Krejci.—On dioxalate of rubidium and its preparation from rubidium alum, by Prof. F. Stolba.—On the survey of the iron-ore mountains in the Chrudim and Caslau districts in Bohemia, by Prof. J. Krejci.—On the relation existing between certain fossil floræ and land-faunæ, and between them and the simultaneous marine faunæ, in India, Africa, and Australia, by Dr. Otakar Feistmantel.—On the variability of *Carabus Scheidleri*. Fabricius, by Jos. Korensky.—On some hydrometrical researches and apparatus, by Prof. R. A. Harlacher.—On a peculiar formation of loops in the cerebral and spinal blood vessels of saurians, by Dr. Josef Schoebel.—On some new vegetable bastards in the Bohemian flora, by L. Celakovsky.—On two new Epilobiæ, bastards in the Bohemian flora, by K. Knaf.—On the capillaries in the mucous membranes of the throat of naked amphibia, with report on a new method of performing injections, by Jos. Schöbl.—On the combination of chlorine with cymol at boiling heat, by B. Raymann.—On the blood vessels of the eyes of cephalopoda, by Jos. Schöbl.—On the origin and period of storms, by K. W. Zenger.—On the deposits of iron ores in the Silurian formation of Bohemia, by K. Feistmantel.—On a new quercitrine sugar, by K. Kruis.—On the travelling routes of migratory birds in Asia, by Joh. Palacky.—Results of the analysis of the Sazava water, by A. Belohoubek.—On the conglomerates of the so-called iron-ore mountains, by Joh. Krejci.—On the Bohemian tertiary flora, by the same.—On the elevation of Carlsbad and its surroundings above the sea level, by K. Koristka.—On the results of some experiments made with a view of growing plants in artificial soils and extending over two years, by F. Farsky.—On some compounds obtained from cholesterine, by R. Preis and B. Raymann.—On the action of iodine upon aromatic compounds, by the same.—On orthobromo-benzoaldehyde, by the same.—On the action of fluoride of silicon upon organic hydroxyl compounds, by the same.—On two sulphosalts of chromium, by the same.—Observations on the reduction formulæ, converting Miller's symbols of the isoclinic system into Naumann's symbols of the hexagonal system, by J. Krejci.—On the employment of oxalate of lead for determining the tenor of Chamæleon solution, by F. Stolba.—On the employment of glass tubes for decomposing steam by means of red-hot iron, by the same.—On the Moravian lepidolite, by the same.—On the separation of cæsium and other alums by means of crystalisation, by the same.—On the preparation of compounds of didymium and lanthanum free from cerium, by the same.

THE *Bulletin de l'Académie Impériale des Sciences de St. Pétersbourg* (tome xxv., No. 4) contains the following papers of importance:—Observation of the passage of Mercury across the sun's disk on May 6, 1878, by A. Sawitsch.—Histological researches on the smaller brain of *Petromyzon fluviatilis*, by A. Jeleneff.—Researches on the Jurassic flora of Russia, by J. Schmalhausen.—On the action of light upon the irritability of the skin of the common frog, by N. Wedensky.—Enumeration of all the Salsolaceæ hitherto found in Mongolia, by Al. Bunge.—General observations on comets, by Th. Bredichin.—Observations of Uranus and Neptune during 1878, by A. Sawitsch.—On the nitro-compounds of toluol, by J. Barsilowsky.—Preliminary communication regarding the appearace of Encke's comet during 1878, by O. Backlund.

THE *Verhandlungen des k.k. geologischen Reichsanstalt* (No. 11, 1879, Vienna) contain the following papers:—On some eruptive rocks from Bosnia, by C. von John.—Researches on the flora of the diatomaceæ-slates of Kutschein, near Bilin, by Johann Sieber.—Notes on some Austrian minerals, by Rudolf Scharizer. The minerals treated of are columbite (tantalite) serpentine, pyrope and pseudomorphous garnet.—On the quaternary formation in Thracia, by A. M. Petz.—On the black porphyry from the

Hallstadt Salt Mountain, by Fr. von Hauer.—Travelling sketches from Bosnia (Travnik), by Dr. Edmund von Mojsisovics.—Another sketch, describing the route from Serajevo to Mostar, is by Dr. A. Bittner; and a third one, on the route from Vares to Zwornik, by Dr. E. Tietze.—On some ammonites from the Carpathian sandstone, by C. M. Paul.

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, September 15.—M. Daubrée in the chair.—The following papers were read:—On linen cloths dyed bluish black, with the intention of replacing the indigo blue cloths employed in the uniforms of the French army, by M. Chevreul. The blue matter in certain military cloths examined, he is able to say is neither indigotine, nor Prussian blue, nor ultramarine; it may be from aniline, and he is inquiring into this.—Experiments tending to demonstrate the compound nature of phosphorus, by Mr. J. N. Lockyer. Phosphorus heated in a tube with copper gives a gas which shows the spectrum of hydrogen very bright. Phosphorus alone, heated in a Sprengel vacuum tube, gives nothing. Fixed at the negative pole in a similar tube it gives very abundantly a gas which shows the spectrum of hydrogen, but which is not PhH_3. The author also describes experiments with sodium, magnesium, lithium, &c. —Researches on erbine, by M. Lecoq de Boisbaudran. The lines of M. Cleve's holmium are precisely those indicated by M. Soret as characteristic of his earth *X*, and the two substances are evidently identical.—The Minister of Agriculture and Commerce called attention in a letter to the common adulteration of olive oil with oils of different sources, and desired the Academy to indicate a practical means of detecting such fraud, which is very prejudicial to cultivation of the olive.—Observations of Hartwig's comet and Palisa's comet, at the Paris Observatory, by MM. Henry.—Observations of the sun during the second quarter of 1879, by Signor Tacchini. A certain increase in the energy of solar phenomena is perceptible. The hydrogenic protuberances were about equally distributed to the north and to the south (instead of nearly all in the boreal hemisphere, as in the previous quarter). The maximum of frequency is between parallels 30° and 60° in both hemispheres. The preponderance of protuberances in the northern hemisphere seems characteristic of the minimum of solar activity. The maximum of frequency of faculæ is found between parallels 10° and 30° in each hemisphere. The author considers we passed the minimum of solar activity in the beginning of this year. A metallic eruption was observed on June 19.—On the spectra of earths forming part of the group of yttria. A claim of priority with regard to what M. Cleve observed.—Determination of organic nitrogen in natural waters, by M. Pellet. He describes a method which is simpler than that given by M. Lechartier recently.—On the oxidising action of cupric oxide, transformation of acetic acid into glycolic acid, by M. Cazeneuve.—New experiments on the mode of action of chloral regarded as an anæsthetic, by M. Arloing. He concludes that chloral is decomposed into chloroform and alkaline formiates in the blood of animals; that the anæsthetic effects are due to chloroform; and that the alkaline formiates mechanically favour their production by increasing the velocity of the circulation, and thus facilitating the impregnation of the nervous elements by the anæsthetic agent.—M. Wolf's "History of Swiss Geodesy" was presented.

Vienna

Imperial Academy of Sciences, June 19.—The following among other papers, were read:—On the products of decomposition from albuminoids through action of oxymuriatic acid, by Herr Horbaczewski.—Researches on the influence of illumination on penetration of radicles into the ground, by Herr Richter. —On some fresh-water fish of South America, by Dr. Steindachner.—South Japanese annelids, by Dr. Marenzeller.—Observations of refraction on several summits, by Herr von Sterneck.—Fauna of the lias brachiopod line of Sospirolo, near Belluno, by Dr. Uhlig.—Brachiopod fauna of the oolite of Balin, near Krakaw, by Herr Sjaknocha.

July 3.—Prof. Brühl presented the first thirteen parts of his Zootomia of all animal-classes.—On some plane rational curves of the fourth order, by Herr Bobek.—On a direct measurement of the work of induction, and a determination therefrom of the mechanical equivalent of heat, by Prof. von Waltenhofen.—On a peculiar mode of producing the orthogonal hyperboloids, &c., by Herr Ruth.—On the crystallisable constituents of corallin, by Herr Zulkowsky.—On continued fractions, by Prof. Gegenbauer. —On the phosphorescence produced by electric rays, by Herr Goldstein.—On some consequences of the Young-Helmholtz theory, by Herr von Brücke.—Prehistoric settlements and burial places in Krain, by Herr von Hochstetter and Herr Deschmann. —On the radiometer, by Dr. Puluj.

July 10.—Prof. Fric presented a part of his work on fauna of gas-coal and limestone of the Permian formation in Bohemia.—On the behaviour of the bacillus of splenic inflammation under extreme low temperatures, by Prof. Firsch.—Researches on the mechanical behaviour of the acinus glands, by Prof. Stricker and Dr. Spina.—Researches on the structure of the envelope of the cerebrum, by Prof. Stricker and Dr. Unger.—Comparative anatomy of the wood of Ebenaceæ and their allies, by Herr Molisch.—Chemical studies on pemphigus, by Dr. Jarisch.—On glycyrrhizin, by Dr. Habermann.—On some derivatives of dimethylhydrochinon, by Herr Kariot.—On the crystalline structure of apophyllite, by Prof. Rumpf.—On the double formation and optical properties of chabasite, by Herr Becke.—On the camphene of borneol and camphor, by Herr Kachler and Herr Spitzer.—On homocinchonidine, by Herr Skraup.—On chinine, by the same.—On Gay Lussac's hypochloronitric acid, by Herr Goldschmidt.

July 17.—Researches on the liverworts, by Prof. Leitgeb (treating of "Anthoceroteæ").—On the cause of excitation of electricity on contact of heterogeneous metals, by Dr. Exner.—Studies on the development of ferns, by Prof. Leitgeb.—On the distribution of arsenic in the animal organism after ingestion of arsenious acid, by Prof. Ludwig.—Contribution to a knowledge of the action of the *nervus vagus*, by Herr Wagner.—On the constitution of cinchonine and cinchonidine, by Dr. Skraup.—Observations on the differences of the two electric states, by Herr Doubrawa.—On the velocity of propagation of sound in tubes, by Dr. Tumlirz.—On the magnetisation of iron rings, by Prof. v. Ettingshausen. —Contributions to a knowledge of elastic reaction, by Prof. Streintz.—On nephrite and bowenite from New Zealand, by Dr. Berwerth.—On the optical orientation of plagioclase, by Herr Schuster.—On new and rare fishes, by Dr. Steindachner.—On idrialine, by Dr. Goldschmidt.—On nitroprussides, by Herr Bernheimer.—On direct introduction of carboxyl groups into phenols and aromatic acids, by Herr Senhofer and Herr Brunner.—Geological observations in the region of the Thessalian Olympus, by Herr Neumayer.—Ditto in the north-east and south-west of the Peninsula of Chalcidice, by the same, and by Herr Burgerstein.—Geological formation of the Island of Cos, &c., by Herr Neumayer.—New researches on cerebral ganglions and the med. obl., by Dr. Meynert.

THE GREENWICH METEOROLOGICAL OBSERVATIONS

Reduction of Greenwich Meteorological Observations. Barometer, 1854–1873; *Air and Moisture Thermometers*, 1849–1868; *and Earth Thermometers*, 1847–1873. Made at the Royal Observatory, under the Direction of Sir George Biddell Airy, K.C.B., Astronomer-Royal. (London, 1878.)

AN important contribution has recently been made to the meteorology of England by the Astronomer-Royal in the issue of this volume, which contains elaborate discussions of the photographic records of the barometer from 1854 to 1873, of the photographic records of the dry-bulb and wet-bulb thermometers from 1849 to 1868, and of the eye-observations of the thermometers whose bulbs are sunk to different depths in the ground from 1847 to 1873. The photographic apparatus and the details of the instruments and their mounting are fully described, and the methods for the reduction of the photographs to numbers, and the discussion of the results, are explained at length.

There can be no doubt that in these twenty years' averages we have the closest approximation to the mean monthly diurnal inequality of the barometer, in other words, to one of the prime factors of the meteorology of Greenwich. Of special interest are the results for the warmer months of the year, which class Greenwich among the places in middle and higher latitudes, whose climates are more or less continental in their character—these more special features being the occurrence of the forenoon maximum as early as 9 A.M., and a marked diminution in the amount and amplitude of the morning minimum. The almost strictly local character of the diurnal phases of atmospheric pressure, as disclosed by the observations at Greenwich, is seen from the occurrence of the A.M. maximum an hour earlier at Kew, where also the A.M. minimum becomes still less pronounced than that of Greenwich. On the other hand, at Falmouth, the A.M. minimum is much the greater of the two daily minima, and the A.M. maximum is delayed from two to three hours later than at Greenwich. Hence the true value of the Greenwich results can only be appreciated after a comparison has been made between them and the results obtained from other meteorological observatories.

An extremely interesting discussion has been carried out, showing the relations between the diurnal inequality of pressure and the different directions of the wind for the months. The results, while showing the double maxima and minima, show also in every case that the diurnal curve is thrown up or down, sometimes very considerably so. The reason for this uptilting of the curves or the reverse, is readily seen if we refer the phenomena to the European storms which affect the winds and pressure at Greenwich in their eastward course. Thus E., S.E., S., and S.W. winds, being in the front segment of storms, are accompanied with a falling barometer, and consequently the curves of diurnal inequality of pressure for each of these winds appear thrown down, most so in case of S.E. winds; whereas W., N.W., and N. winds which prevail in the rear of storms and are attended with a rising barometer, present curves which are thrown up, the uptilting with N.W. winds being remarkably great. These effects are most decided during the stormiest half of the year.

The observations of temperature are discussed with particular fulness, and the length of time is sufficient to give curves showing a diurnal inequality of temperature such as will substantially represent the curves for large portions of the south of England, not bordering the sea, where the thermometers are similarly placed to those at Greenwich.

The curves of temperature for the different winds have also been worked out with much elaboration, and give most interesting results. We would refer specially to the diagram on page 18, showing the air-temperature curve for December, with the diurnal curve for the same month, when the N.W. wind blew, from which it is seen that while the curve for N.W. winds has substantially the same form as the general curve for the month, it superadds a gradual fall of about 4°·0 during the twenty-four hours. On comparing the temperature of the air at midnight with that at the following midnight, it is shown that a clear sky lowers the temperature considerably in November, December, and January, but raises it in other months, particularly in May, June, and July; whereas an overcast sky scarcely disturbs the temperature, so that on an average it stands at the same point at the end as at the beginning of the twenty-four hours. On the average of all months the N. wind is the coldest, the S.W. the warmest; the order as regards temperature, beginning with the coldest, is N., N.E., N.W., E., S.E., W., S., S.W.—an order, however, which differs in different months. The results of changes of wind differ greatly with season; thus a change of wind from N.E. to S.W. raises the temperature 11°·0 in January, but only 0°·3 in June.

The earth thermometers were made under the superintendence of the late Prof. J. D. Forbes, and placed in position in 1846, the graduation of these thermometers having been made by Prof. Forbes himself. The hour of observation has been noon, but during 1846-47 observations were made every two hours, from the results of which "corrections" have been obtained for the reduction to approximate mean temperatures. The following are among the more important results:—

	Earth thermometers at depth of				
	1 inch.	3·2 feet.	6·4 feet.	12·8 feet.	25·6 feet.
Mean coldest month . . .	Jan. 40°·38	Mar. 42°·48	Mar. 44°·79	Apr. 46°·42	June 48°·94
Mean warmest month . . .	July 64°·34	Aug. 61°·38	Aug. 59°·60	Sept 55°·74	Nov. 52°·21
Difference . .	23·96	18·90	14·81	9·32	3·27
Mean annual temperature	51·24	51·13	51·53	50·87	50·55

The mean temperature of the air from observations made with a thermometer in the perforated wooden box protecting the projecting scales of the thermometers is 51°·59. But with the view of giving a more exact comparison between the temperature of the air and that of

the earth, a table (p. 100) of the mean monthly temperatures of Greenwich from October, 1846, to December, 1873, is given. The method by which this table was constructed is thus described :—

"The values for 1847 are the simple means of two-hourly observations; those for 1848 are the means of usually six observations daily, corrected for diurnal inequality by application of corrections derived from Mr. Glaisher's paper 'On the Corrections to be Applied to Meteorological Observations,' in the *Philosophical Transactions* for 1848, Part I. The means for 1849 and all succeeding years are found by combining eye-observations, taken usually four times on each day, and corrected for diurnal inequality, with observations of the maximum and minimum corrected by a quantity (taken from Mr. Glaisher's paper) peculiar to the period of the year. These temperatures may be regarded as accurate mean temperatures."

From this table the annual mean temperature of Greenwich comes out as 49°·43, being 1°·9, 1°·7, 2°·1, 1°·4, and 1°·1 in excess of the earth thermometers from the surface downwards. This large excess raises a doubt as to the correctness of the method adopted in calculating the mean temperature at Greenwich. Looking at Table 43 we find the mean temperature at every hour of the day for the month of June, with the number of days each, of the years for which observations were available for striking the means. On eight of the years the record was complete, and on these years, therefore, the mean temperatures deduced by the two methods should agree closely, if the method of calculating the means quoted above be a correct one. A comparison shows that in none of the months is there any agreement, the extreme differences being 1°·5 for June, 1865, and 0°·7 in June, 1863, and the mean difference for the whole eight years, 1°·0. The true mean—that of the twenty-four observations each day—is in all these cases in excess of the other mean. Similarly May, October, and January were examined, with resulting mean differences of 0°·5, 0°·3, and 0°·2 respectively. It follows that the mean temperatures, which are the most important element in the climate of Greenwich, remain still to be calculated.

When this has been done it will probably be found that the mean annual temperature of Greenwich has been understated by half a degree, and that consequently the mean for the twenty-eight years ending with 1873 was 50°·0. This supposition is rendered the more probable by applying the noon correction from Greenwich daily inequality tables to the mean of the temperature inside the perforated box protecting the earth thermometer. The mean annual temperature then becomes 50°·1.

In a large number of the years the third barometric maximum, first noticed by Rikatscheff as occurring in certain regions of the globe a little after midnight, appears in the Greenwich diurnal curves for December, January, and February, less frequently in March, and seldom or not at all in the other months. The somewhat rough method which has been adopted in reducing the barometric observations to 32° unfortunately renders the evidence furnished by the Greenwich results regarding the more refined inquiries of meteorology, such as this, and the mean diurnal inequality of the barometer in the lunar months, not so satisfactory and conclusive as might have been wished.

ALEXANDER BUCHAN

CHEMICAL DENUDATION AND GEOLOGICAL TIME

Chemical Denudation in Relation to Geological Time. By T. Mellard Reade, C.E., F.G.S., Past President of the Liverpool Geological Society. (London: David Bogue, 1879; pp. 61).

THIS little book is made up of three papers: one on "Geological Time;" a second on "The Geological Significance of the *Challenger* Discoveries;" and the third on "Limestone as an Index of Geological Time." The last paper was read before the Royal Society in January, 1879, and the others have been read before the Liverpool Society, of which the author is a distinguished member. Although, therefore, not new, these papers are well worth reading, for a vast amount of good solid fact is environed by curious calculations, and by hypotheses of a highly exciting nature. That is to say, exciting to the prosy realistic disposition of modern geology. This meritorious work, however, is slightly depreciated by the introduction of matter which is not strictly consistent with the results of modern research. Nevertheless, on the whole, the work may be considered very satisfactory by those who believe that doubt is the mother of progress; for all the hypotheses and conclusions in it are the product of a geological imagination of the highest and most vigorous order, and are of course open to objection. In the introduction it is stated that the author, during an attempt to estimate the amount of "solid matter conveyed annually in solution" in river-water to the sea from the surface of England and Wales, had a "new modulus" come into his mind, which might enable him to gauge the vista of the immensity of past time, or rather to arrive at "a minimum limit to the age of the earth." The result is thus stated: "If we imagine the area of England and Wales consisting of 58,300 square miles, to form one river-basin, the delivery of water by such river would be 68,450,936,960 tons, or 18·3 inches per annum, containing a total of 8,370,630 tons of solids in solution, representing a general lowering of the surface from that cause alone of ·0077 of a foot per century, or one foot in 12,978 years." Taking the "soluble denudation" of other parts of the world into consideration, Mr. Reade considers "that about 100 tons of rocky matter is dissolved by rain per English square mile per annum." This he states contains 50 tons of carbonate of lime, and twenty of sulphate of lime, &c., and proceeds: "If, as is generally supposed, the sea contains only what is washed into it from the land, and we can estimate its numeral contents in tons, we at once get a minimum measure of the age of the earth." As Herschel states that the ocean contains 2,494,500 billions of tons of water, and the mean of Dr. Frankland's analysis gives 48·9 tons of carbonate of lime and magnesia, and 1,017 tons of sulphate of lime and magnesia in 100,000 tons, it follows, according to the author, that it would take 25,000,000 of years to accumulate the quantity of sulphate of lime and magnesia contained in sea water, but only 480,000 years to renew the carbonate of lime and magnesia, and the discrepancy is caused by the appropriation of the calcic carbonate by mollusca for their tests. The amount of visible sediment brought down mechanically by rivers, as calculated for the whole world upon the results of Humphreys and Abbot for the Mississippi, and the

estimate is given at six times the amount of the soluble matters. This produces over the whole globe an amount of denudable matter equal to 600 tons a square mile per year. Going back in all time at this rate, and allowing for coast erosion, glaciers, &c., the ten miles of sedimentary strata must have occupied 526 millions of years in accumulation. The author readily disposes of Sir William Thomson and tidal retardation, and his limits of time. His calculations are "fallacious through leaving out agencies that we know are at work, and which the calculations I have submitted bring out in greater force."

He admits that he does not know how deep the sedimentary strata are, and it does not appear to have entered into his calculation that there was from the beginning carbonate of lime and sulphate of lime in sea-water, that the rainfall must have varied during geological time, and that the denudation of the surface has brought rocks of different solubilities within the reach of rain. Again, his calculations are vitiated by the fact that a vast amount of water percolates through many kinds of strata and does not come into the neighbouring river valleys, and that there are great artesian collections not in communication with the sea. In fact, one of the great problems of the day is to explain what becomes of vast quantities of such water. We must leave the author to settle with Prof. Geikie all those interesting calculations which are founded upon the hard and fast lines of uniformity.

There are some remarkable statements in this essay. Thus Hutton "laid the foundation of our present knowledge of physical geology." He gave us the grand method of geological study, but certainly many of the facts were well known before his time, and others have had no relation to his researches or method. Then there is the curious notion resuscitated as "a result of the *Challenger* expedition," that the calcareous portions of the dead foraminifera are dissolved by the carbonic acid in the sea before they reach the bottom. There are calcareous organisms in the red clay nevertheless, but perhaps they have escaped. It was a pretty idea that Thomsonian myth of the nymph Globigerina sinking into the arms of Neptune, and falling blushing and nude on to the abyssal floor, turned, like Adam, into red clay. But myths are not science, though there is a science of myths. In his paper on the *Challenger* discoveries, the red clay is a terrible incubus; and the following quotation will show that the author's physics are sometimes confused:—

"Now, this lowering of the bottom temperature over such immense areas is certainly a remarkable and unexpected fact, and shows that the secular cooling of the earth must be extremely slow, as to all appearances contact with the bottom does not in any case appreciably influence the temperature of the bottom water."

As a matter of fact the author is wrong in giving the *Porcupine* credit for discovering the great extension of the globigerina ooze, and he is not justified in calling the nodules of the red clay peroxide of manganese, for there is much iron in them, and he has been misled as to their vast quantity.

One of the funny notions of some scientific thinkers meets with no favour from Mr. Reade, whose geological knowledge is practical as well as theoretical. They consider that because the older rocks contain nothing like the present red clays, &c., of the ocean floor, that the oceans have always been in their present positions. Mr. Reade points out that the first proposition is not that proven, and the distribution of animals and plants and the fact that the bulk of the strata on land are of marine origin are opposed to the hypothesis. He very properly waits with the rest of the world for the final publication of the *Challenger* facts, and in the meantime enjoys the theories.

In the last of his papers the author begins by asserting that "The geological history of the globe is written only in its sedimentary strata." He proceeds to state that limestone rocks have been in process of formation from the earliest known geological period, and measures the absolute quantity of carbonate of lime in the sedimentary rocks. The depth of these he tries to estimate by borings! by the cañons of Colorado!! by the denudation of Suliven!!! by the amount of downthrow of faults and the thickness of the strata of mountain masses. In fact by every way except the right one, by the process of the gathering section. He considers that one mile is about the average thickness of the sedimentary crust, and that one-tenth of it is limestone, or 528 feet enveloping the globe. On the strength of former calculations, he believes that one foot of this universal stone would take 1,139,032 years to accumulate, or that in round numbers—a million or two are nothing in the way of argument—the whole occupied 600 millions of years, and this is the minimum age of the earth since the first Laurentian sediments. Mr. Reade has given a number of most valuable facts in his book relating to water flow and soluble matters, and his readers will pardon him for running a little riot in his theories.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Colour-Blindness.

THE normal perception of colour, according to the Young-Helmholtz theory, depends on the coexistence in the retina of three sets of nerves capable of conveying three distinct sensations, and excited most strongly by ether-vibrations of three distinct rates. The simple sensations conveyed to the sensorium by these nerves are known as primary colours (red, green, violet), and all other colour-sensations are produced by combined action of at least two out of the three in various proportions. Dichromic vision is explained by the absence of one of the three primary sensations, in most cases that which corresponds to the long-wave sensation, red.

Dr. Pole points out, in his article (NATURE, vol. xx. p. 477) that this hypothesis does not account for the most typical condition of colour-blindness, such as he describes in his own case. It seems to me, however, that a slight modification of the theory is all that is necessary to obviate this objection.

I would suggest that the nerve-fibres are not always most strongly excited by exactly the same wave-length, or, in other words, that the primary colours are not precisely identical in all normal eyes. There may well be small differences, and it is only when the divergence is great that the differences are appreciable and "colour-blindness" is noticeable.

Such a purely personal and subjective question as whether all normal eyes are similarly affected by similar light-waves is, of course, difficult to determine; but at least it is possible that a very slight structural difference in the nerve-ends of the retina may occur, sufficient to render them excitable chiefly, let us say, by the more rapid waves at the sodium line D, instead of the slower waves of line B.

In Dr. Pole's typical case of dichromic vision, the sensation which is absent is the middle one, and the two existing sensations are not both identical with those in normal eyes, but have their maximum impressions produced by vibrations whose rates are nearer together, so as not to leave the retina insensible to the middle of the spectrum. His long-wave colour corresponds with the sodium line D, which is therefore a primary to him, and his short-wave primary is probably violet; green light, accordingly, causes very little sensation, or will appear yellowish or bluish, as its vibrations come within the scope of one or other of the two existing sets of nerves.

It appears to me, *à priori*, that it is not unlikely, in the case of the absence of the intermediate (green) sensation, that the other two sensations should become approximated, so as to be of more use in discriminating a continuous series of colours; and such an "equilibration" is analogous to the hyper-sensitiveness of touch or hearing to which a blind man attains, one channel of communication with the external world the more readily lending its aid when another is closed.

This hypothesis of *individual differences in the primary colour-sensations* seems satisfactorily to remove the apparent violence done to the facts of dichromic vision by the Young-Helmholtz theory, and to accord with all other evidence of the physical basis of perception of colour.

Prof. Mivart on "Tails"

IN the Davis lecture (NATURE, vol. xx. p. 509), Prof. St. George Mivart remarks that kangaroos use their tails "to a certain extent in their long jumps." This may either mean that the tail is used as a balance to the fore-part of the body—as, of course, is the case—or as a means of propulsion. The latter is the natural inference to be drawn from the sentence.

The belief that kangaroos thus actively employ their tails is of wide extent in Australia, but a residence there of over three years, principally in the bush, so thoroughly convinced me that the idea was erroneous that I think I am justified in challenging the Professor, if I have not misinterpreted him, to give the evidence on which his statement is based.

As we have recently learnt, through photographs of a galloping horse (*vide Field*, June 28, 1879), eye observations, where movements are rapid, are not entitled to much weight; but still, as I have seen many hundred kangaroos pass at full speed, and have observed them especially in reference to this question, some little dependence may be placed on my assertion that the action of one of these animals in full stride is incompatible with the use of its tail as a third hind leg.

In the descent of the kangaroo in each leap, the tail swings freely upwards to a curve, whose arc is at about right angles to the slope of the back, and during the rise of the succeeding leap it falls, and is then apparently impeded by muscular action. Were the tail actively employed, it would have to strike the ground almost at the same moment as do the feet, and the whole form of the animal would be altered. The tail would have to be brought down rapidly, like a riding whip, whilst the upward swing would be retarded.

From the forward slope of the body in long leaps and the fact that then, of the hind limbs, only the feet touch the ground, it is evident that the portion of the tail that alone could be employed as a propeller would be the posterior and weaker part.

Again, if we consider the speed of the kangaroo over the ground—say, 15 miles an hour, or 7½ yards in a second—we find that only length of bones and mobility of joints of the hind legs permit the feet to rest on the same spot of ground for even a fraction of a second. With the tail it is otherwise; in the position it is carried by the animal it must travel over the surface for some two feet, though but pressed against the ground for a tenth of a second. I fear not even the callous under-surface of a kangaroo's tail would long stand such terrible attrition.

If further evidence is wanted, it is to be found in the tracks left by kangaroos, wallaby, &c., that have travelled quickly over sand, mud, &c. There is seldom to be seen the mark of a tail, and then only as a graze. The very tendons of the tail are an argument against its utility in leaping, for those on the upper side are twice as powerful as those on the under.

In conclusion let me say that it has been suggested to me that the remark about kangaroos making use of their tails to carry grass might lead to the supposition that their tails are prehensile.

E. H. PRINGLE

Beckenham, September 29

IN Prof. Mivart's interesting lecture on "Tails" the statement occurs that kangaroos "make use of their tails to a certain extent in their long jumps." This I believe to be an entire misapprehension. No doubt the massive tail of a kangaroo suggests the possibility of such use, and the idea is helped out by the very obvious employment of its tail by the animal in almost all its slow movements, when it rests of necessity on the ground. In leaping, however, the body is thrown forward at an angle which raises the tail from the earth. On the great sandy flats about the shores of Moreton Bay, kangaroos have often afforded me the opportunity of convincing myself that the tail touches the earth only occasionally and very lightly, probably when the balance of the body is not perfectly maintained. I have traced the marks of the great hind toes over this sand when damped by rain, and in the best condition to take the slightest impression, and have never found anything more than a *very faint* mark now and then, and that evidently such as had not been produced by any effort of the animal to urge itself onward by means of its tail. In one instance the track of a kangaroo, which had crossed a flat within sight of me at full speed, happened to cut the track of some small wading bird, which enabled me to compare the deep holes made by the powerful stroke of the hind legs with the shallow oval mark made by the tail, about half a dozen times only in a distance of about four hundred yards, and the track of the bird. Had any propulsive force been used, this mark must have been very distinct on a surface capable of taking a perfect impression of the bird's foot. The rock kangaroos leap in exactly the same manner as their larger congeners, yet their long and comparatively slender tails could hardly be supposed by any one to render them any assistance. Even in the confined space allotted to them in the Zoological Gardens it may be seen that kangaroos leap without any help from their tails, and when they are going very fast the axis of the body is thrown forward into a position approaching the horizontal, and the tail is then quite clear of the ground. Prof. Mivart is not singular in his misapprehension on this point, for I find in Prof. Alleyne Nicholson's "Manual of Zoology," edition 1875, p. 580, that "the tail is also extremely long and strong, and by the assistance of this organ and the powerful hind limbs, the kangaroos are enabled to effect extraordinarily long and continuous leaps."

ARTHUR NICOLS

About Snakes

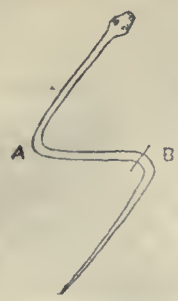
HOW do snakes progress? I ask this question in full knowledge of all that has been written on the subject, and nought that I have read satisfies my mind nor meets all requirements. The books tell us that the ribs of the snake are its legs. All well and good, as long as we are dealing with smooth plane surfaces and sluggishly moving snakes, as the boas; but the theory utterly fails with snakes which literally fly through grass, or climb trees or walls with equal facility. On one occasion I allowed a boa to pass over my hand pressed flat on the ground, and I distinctly felt the onward movement of the rib legs, acting exactly like the outside legs of the centipede, and I felt quite satisfied that, under the circumstances, the snake was moving by means of its ribs.

But this timid and harmless rat snake, which you see absolutely flying through the grass to escape you, cannot be moving by the aid of its ribs; for first, there is nothing for them to act on, and secondly, you cannot imagine the ribs acting rapidly enough to ensure the immense speed at which the animal passes through the high grass. Look at this tree snake surveying you from a bough; how did it get there? The books will tell you, by winding itself round the tree, and thus progressing upwards; but a slender snake of 12—18 inches in length cannot grasp a trunk 2 feet in diameter for the first start up the tree, and so it must get up some other way.

How did this little snake 9 inches long ascend the side of a glass jar 10 inches high, and assume the position I shall presently describe? Certainly its rib legs gave it no assistance.

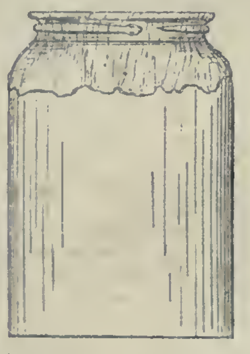
The man who brought the boa, had with him an earthen pot full of small ash-coloured snakes, quite new to me, and I never saw ferocity and activity more remarkably combined than in those small reptiles; on taking them out by the handful, they fastened their jaws (well armed with teeth) upon the man's hand and wrist, and hung like gigantic leeches. Accustomed to such attacks, the snake owner removed the little demons, each separately, with some difficulty, and the wounds bled freely. But the activity, and mode of progression in these snakes interested me more than their ferocity; thrown on the ground they

immediately assumed this figure, and then began to fly about in



all directions, requiring some trouble and agility in re-collecting them. I analysed their progression carefully, and found it to be both progressive and retrograde, the former predominating. The body at B seemed to become rigid for a second, allowing the upper part A to be thrown, not *crawled*, forward, and thus for a second the animal was straight; then A, with a slight retrogression, became rigid, and B advancing, the animal assumed the shape shown. It advanced with astonishing rapidity by a series of jerky undulations. In fact, making full allowance for friction, the snake swam on land, and its rib legs were of no use whatever to it in progression.

Now let me say a few words about the small snake in the glass jar, and I shall then be in a position to advance my ideas about anguine locomotion. As before mentioned, I placed the little creature (a harmless one) in a large glass jar ten inches high, and stretching a bit of coarse muslin over its broad mouth, secured it by an elastic band. A day or two after, I was much surprised to find my snake gone, and more so to find the muslin band and elastic ring intact. No one had touched the jar, for a wholesome dread of snakes existed in the house, but yet the little animal had disappeared. On closer examination I discovered it *coiled outside the neck of the jar below its lip, and between the muslin and the glass*, thus—



How did it get there?

Deeply interested, I replaced the snake in the jar, and carefully watched its attempts to resume its strange position. I found it had no difficulty in ascending the side of the jar and standing erect on its tail, and its movement in doing so was graceful, unconstrained, and directly upwards. Watching more closely, *I saw the snake distinctly adhering to the glass*, its abdominal scales creating a vacuum exactly like the pedal scales of the common house-lizard. *There was not a doubt of it*, and I felt quite satisfied as to how snakes get into the strange localities in which they are found out here, and which I shall presently describe.

In many native huts you find cupboards extemporised by building round earthen pots, called gharrahs, into the mud walls, their mouths being flush with the smooth plastered walls, and about four feet from the ground, and one from the slope of the thatched or tiled roof. Cobras often are found coiled up in these pots, and the first intimation is the fatal strike at the hand of any one rummaging in the pots. How did the snake get there? "Off the roof to be sure;" but how did it get on to the roof of an isolated hut with smooth mud walls? How did the deadly kerarts get up into my bookshelves, where I have often found them coiled up on my books. Of the deadly snakes, this is the only one of a literary turn, and it is frequently found among books, a rather dangerous haunt for those who frequently refer to them. How did the cobra get into the double roof of my brougham, and frighten my wife out of her wits by wishing to share its interior with her? How did another get into the sleeve of my wife's dress, which was hanging two feet from the ground, on a wall peg?

I believe terrestrial snakes move in one or other of the following ways:—

1. On smooth plane surfaces, by means of their rib legs; *e.g.* the boa.

2. Through high grass, by a rapid, almost invisible, sinuous onward movement, as the hydrophidæ in water; *e.g.* the rat snake.

3. Climbing trees, or ascending smooth surfaces by erecting their abdominal scales (for climbing) or using them to produce a vacuum, as lizards do their foot scales for ascending smooth surfaces, *e.g.* tree snakes and cobras in native cupboards.

Deglutition in Snakes.—Soon after the capture of my little snake of the glass jar, I presented it with a frog, and watched proceedings. And here let me note that the snake was 9 inches long, with a delicate little head not ½ an inch broad, while froggy was 2 inches long and 1 broad. Bearing in mind the old puzzle, "What's smaller than a mite's mouth?" "That which goes into it"—I watched proceedings with great interest, and was well rewarded, for the snake immediately seized froggy by the nose, the animal making desperate attempts with fore and hind-legs to shake it off, but all in vain. All this while the process of deglutition (?) was going on remorselessly, or rather, the snake was slowly but surely getting outside the frog, and in this fashion: by a sort of vermicular process you could see the sharp little teeth advance a little, and then the whole body wriggle up to the new hold on froggy's head. And so it very gradually disappeared; then came the shoulders, and the arms followed, pressed against the sides. When the teeth reached the sacrum the legs were violently convulsed, then they disappeared, and last of all the toes, and the snake was fairly outside froggy. Overjoyed, he rubbed his lips against the sides of the jar, gave two yawns, and then composed himself to digest. The whole process lasted exactly half an hour.

Snake Charmers.—I had not been many years in India when I had an excellent opportunity of seeing the so-called snake-charming, and of satisfying myself that it was only clever *legerdemain*. A couple of snake-charmers appeared in the compound and offered to purge it of all the snakes it contained. I embraced the opportunity with great alacrity, but insisted on dictating my own terms, which, after some demur, were agreed to. I selected one man (the other remaining with the baskets), and offered him the choice of accompanying me, either in his dhotee[1] only, and a bare head; or with his pugree[2] and a langootee.[3] He chose the latter costume, soon made his toilet, and stood before me all but naked. I satisfied myself that the langootee could not possibly conceal a snake, and I had yet to find whence the reptile could, or would be produced. So we proceeded to business, accompanied by a crowd of gaping servants. I led the way to a great prostrate trunk, beneath which a cobra (imaginary) was said to lodge, and here he started his rude bagpipe, and began his incantations and gesticulations. But the snake refused to be charmed, for the very good reason that it was not there, and the charmer could not evade my searching gaze. He now took the lead, and drew up before a tempting looking hole in a bank, where he felt sure he could seduce a snake. "Very well," said I, and we formed a semicircle, in the middle of which he stood, and resumed his incantations. Suddenly, to divert my gaze, he pointed to the hole, and exclaimed, "Dekho, sahib!" (look, master), and in a moment, extracted (apparently) a cobra from it. But he did not see that, in that moment I had observed his hand, like a lightning flash, extract a snake from the folds of his pugree, and simultaneously appear to extract it from the hole. The *modus operandi* was clever *legerdemain*, but unmistakable cheating. One of my servants saw the trick too, and was about to exclaim, but I silenced him with a gesture, and appeared convinced at the marvel. "Now," said I, "as you have found the snake, you must prove to me that it is poisonous," and so a poor chicken was sent for, and placed under a coop with the snake, but here again the snake-charmer overdid his performance, for dislocating the chicken's neck with his finger and thumb as he placed it under the coop, he immediately raised it, and

[1] *Dhotee*, the voluminous waist-cloth worn by all Hindoos.
[2] *Pugree*, the cloth worn round the head.
[3] *Langootee*, a narrow strip of cloth worn between the thighs of the male, just sufficient to hide his nudity.

exhibited the poor animal dead. If it had been struck by the snake, 10-15 minutes would have elapsed before death. I still seemed convinced, and on his coolly asking for the chicken for his dinner, I said I could not think of allowing him to eat a poisoned animal, and so ordered it to be buried.

Having received their bakhsheesh, both men asked me for some brandy: as, at the moment, there was none in the house, and telling them so, one pointed to a large bottle of saturated tincture of ginger which was standing in the sun, and asked what it was. On my telling him, both asked for some, so I bade them sit down, and poured a mouthful down each gullet. The unexpected pungency of the shrub astonished them, but one of them, pressing his stomach with both hands, and with his eyes streaming with tears, gasped out "aur do" (more give). The other man said he had had enough. Both then rose, and shouldering their baskets, salaamed and left the compound.

Skin shedding among Snakes.—Though I have handled exuviæ by the hundred, and some of them just cast, I have never witnessed the process of skin-shedding, nor, I believe, has any observer.

It is well known that the skin is always found inverted, and very often, quite entire; and the general impression is that the snake fixes itself in a bush, or strong grass, and then wriggles out of its skin. But I have found the skin on the floor of a bath room, and on the rough ballast of a railway.

I believe that fixture is obtained by means of the abdominal scales, and that then the *modus operandi* is as follows: the skin ready to be cast, yields round the snake's mouth only, and remains adherent to the extremity of the tail. As the animal advances the caudal extremity of the skin is inverted, that is, pulled inwards, and so the process goes on, and is completed by the tail passing through the mouth of the skin; and thus the direction of the abandoned skin is directly opposite to the direction taken by the skin-casting snake. That is, if the mouth of the skin lies east, the snake went out to the west.

Take the finger of a glove, and pass a knotted thread inwards through its tip, then pull gently on it, and the tip of the glove will pass inwards and downwards, and ultimately pass through the base of the finger, which will now be uppermost.

(*To be continued.*)

A Plague of Rats

I HAVE read with great interest in NATURE, vol. xx. p. 65, a note of Mr. Orville A. Derby's on plagues of rats in Brazil. The same thing occurs sometimes in the south of Chile, Araucania, Valdivia, and Llanquihue, when the Coligue, and other species of the Bambuseæ have flourished and fructified, an occurrence which happens every 15-25 years. These grasses, with solid canes, unbranched, of sometimes more than 10 metres long and 8 cm. thick, flourish only once in their life, when they are 15-25 years old, and then their fruits ripen in astonishing quantity. This causes an enormous multiplication of rats and mice in the woods, animals rather rare commonly; and at the end of the same or the beginning of the next year, these animals have finished with their food, and are then obliged to migrate to the cultivated districts, where they are very noxious. The Indians collect the seeds of the Coligue as food, as the Brazilian natives seem to do with the fruit of the bamboo. I had occasion to observe this fact in 1869 or 1870, when I lived in Valdivia, and when almost all the Coligues of the province flourished at once and died afterwards; and I had heard it already before from the natives. FEDERICO PHILIPPI

Santiago, Chile, August 17

Solar Halo

ON Monday, September 22, about 12 o'clock, on the coast at Burnham, Somerset, my little boy called my attention to a large, clearly-defined, white circle, of which the zenith might be the centre; on the southern side of the circumference was the sun, above which were the arcs of two other circles, one of which was flattened. They united at a small distance above the sun, and displayed rather dull prismatic colours; between the points where these arcs joined the large white circle were two rather oval-shaped patches, also showing prismatic colours. The appearance lasted about an hour and a half. G. MAPLETON

Badgworth Rectory, Weston-super-Mare, September 23

CHEMICAL ACTION

WHY are the properties of bodies so profoundly modified by the action called chemical? Why do *certain* bodies *only* act chemically upon one another? What exact meaning is to be attached to the expression "chemical affinity?"

These questions, and questions such as these, have engaged the attention of chemists since chemistry began to be an exact science.

The products of chemical action are innumerable: chemical science is encumbered with a multitude of compounds, and each day additions are made to the number; but no general theory of chemical action has yet been broached which suffices to explain the known facts.

The consideration of the initial and final distribution of matter in a system upon which chemical action is exerted, has almost entirely engaged the attention of chemists, to the exclusion of the study of the course of chemical change, the conditions modifying this change, and the nature of the force which causes the change.

The molecular theory of matter furnishes us with a fairly complete answer to the question—Wherein consists the essential characteristic of chemical action?

Chemical action, says this theory, results in the production of new molecules, mechanical action results in changes in the rate of motion of existing molecules.

But why are new molecules formed only when certain bodies are brought into contact and not when other bodies are placed under similar conditions?

Because the first substances exert chemical affinity upon one another, whilst the others do not.

But what is chemical affinity?

The expression affinity was originally used to denote a resemblance between certain substances which exerted an action of some kind upon one another. But when the study of chemistry advanced, it was found that those bodies which most readily exerted mutual chemical action, were, as a rule, unlike in their chemical habitudes.

The expression affinity was, however, retained to express the fact that one body exerted chemical action upon another. This affinity could not be measured in terms of any unit, hence chemists were content to draw up tables of relative affinities. These tables were for the most part based upon qualitative reactions, and supplied merely empirical information.

In the year 1780 Bergmann formulated a general theory of chemical affinity: the main points insisted upon by Bergmann were, that the affinity between two bodies is independent of the masses of the bodies brought into mutual contact, and that the value of this affinity is constant under similar conditions. Bergmann further supposed that the relative affinity values of various substances may be empirically represented by the amounts of these bodies which mutually combine together: thus in the formation of a series of normal salts, the affinity of the acid is greatest according to Bergmann, for that base, the greatest amount of which is taken up by the acid. Conversely a base has the greatest affinity for that acid which combines with it in greatest quantity.

The latter part of Bergmann's theory could no longer be upheld when the atomic theory of Dalton had introduced clearer views concerning the quantitative action of chemical substances upon one another. But the atomic theory was not opposed to the view that the affinity between the bodies is independent of the masses of the bodies brought into mutual contact.

In the year 1803 Berthollet published his theory of chemical affinity, a theory which was essentially opposed to that of Bergmann. The French chemist said that the chemical action of one substance upon another is proportional to the mass of the acting body and to its affinity for the second substance. Berthollet thus considered not only the affinity of one body for another, but also the masses

of the acting bodies. He further took into account the physical conditions under which the chemical change proceeded, inasmuch as he regarded chemical decomposition as not completed by chemical affinity alone, but by affinity aided by cohesion and elasticity.

Upon Berthollet's view of affinity, the affinity of an acid was greatest for that base with which it combined in smallest quantity; and a substance with very small affinity for the constituents of another was nevertheless capable of decomposing that other, provided a sufficiently large mass of the first was employed.

No important general theory of chemical affinity has been propounded since the time of Berthollet; chemists have now favoured his views, now the views of Bergmann, the preponderance of opinion inclining generally towards the theory of the French chemist.

In the year 1867 a most important paper, "Etudes sur les Affinités chimiques," was published in Christiania by Professors Guldberg and Waage. This paper has been supplemented by a second communication within the last few months by the same authors: the general theory of chemical affinity has been also materially advanced by three publications made by W. Ostwald, ranging from 1877 to the present year, and entitled "Volumchemischen Studien."

These papers undoubtedly mark an epoch in the development of chemical theory, presenting, as they do, the beginnings of the application of mathematical reasoning to the facts of chemistry, and furnishing, likewise, new methods for solving some of the more intricate problems presented to the chemist.

Guldberg and Waage consider specially the influence of mass upon chemical action. In the general equation $A + B = A' + B'$, where A' and B' represent the new substances formed by the mutual actions of A and B, we have two forces at work, that causing the formation of A' and B', and that tending to re-form A and B; for any given stable condition of the system A, B, A', B', these two forces are in equilibrium. The force causing the formation of A' and B' increases proportionately to the coefficient of affinity of the reaction, and is also dependent upon the quantities of A and B present. If the *active masses* of A and B (that is, the masses of these bodies present in unit volume of the reacting system) be denoted by p and q respectively, and the coefficient of affinity by k, then the force is represented by the expression kpq.

This expression may also be regarded as representing the amounts of A and B, transformed, in unit time, into A' and B'.

By a similar method the expression $k'p'q'$ is arrived at as representing the force which tends to bring about the reformation of A and B. The condition of equilibrium of the system is such that $kpq = k'p'q'$.

If $pqp'q'$ be experimentally determined, the proportion $k : k'$ can be calculated, and hence the limit of the reaction for each initial condition can be determined.

Guldberg and Waage have applied their law of mass action to a number of special cases of chemical decomposition, the more important of which are decomposition of carbonates of the alkalis by barium sulphate, and the reverse action, formation of ethylic acetate and water by the action of alcohol upon acetic acid, division of a base between two acids, decomposition of hydriodic acid in presence of an excess of either iodine or hydrogen, &c.

Those actions which consist of two parts—the direct and the reverse chemical change—are especially adapted for the study of the influence of mass. This class of action is regarded by Guldberg and Waage as complete, while those in which—by the removal from the sphere of action of one of the products of the first part of the change or by other means—the reverse action is not accomplished, are regarded as incomplete. The combination of hydrogen and oxygen, for instance, to form water, is but one phase of the complete action, the other phase of which is the decomposition of water into hydrogen and oxygen; by conducting the first part of this action at a temperature above that of the dissociation temperature of water, the action becomes complete.

In their view of chemical action, Guldberg and Waage regard the molecules of the reacting substances A and B as composed of the atoms $\alpha\gamma$, and $\beta\delta$ respectively; these atoms are supposed to perform their own vibratory movements within the respective molecules. At certain points the force acting between α and γ and between β and δ is supposed to be very small; if, when α and γ are in this position, the molecule B come near to A, an exceedingly small disturbing influence may determine that α and β and γ and δ pair off together, to form the new molecules A' and B'. A similar view is taken of the reverse action whereby A and B are reformed.

Guldberg and Waage consider in detail only the action of mass as influencing the force of chemical affinity, but they also recognise the existence of secondary forces due to the foreign bodies present, *i.e.*, bodies which do not directly undergo chemical change during the reaction under consideration. Among these foreign bodies is to be placed the liquid in which the salts are dissolved whose mutual action is to be studied.

That the degree of dilution of the reacting liquids exerts an influence upon the course of a chemical change is witnessed to by many well known facts. Quantitative measurements of this influence are not, however, numerous.

If a molecular explanation of chemical action be adopted, we should expect to find a marked difference between the modifying influence of physical conditions upon a chemical change occurring in a dilute and the same change occurring in a more concentrated solution.

In the former case, where the molecules of the reacting bodies are comparatively widely separated from one another by those of the diluent, and where possibly a larger amount of energy of motion is associated with each molecule, one might expect that small disturbing influences would produce a marked effect upon the course of the chemical change. And such an effect is produced by small changes in physical conditions.

As one result of experiments in which I have been engaged for some time, I find that when a dilute solution of strontium chloride is mixed with a dilute solution of sulphuric acid (the molecular proportions being as 1 : 3 or 1 : 4), the amount of strontium sulphate produced in a short time—thirty to sixty minutes—is very largely dependent upon such conditions as the manner in which the two liquids are mixed, the smoothness or roughness of the vessel containing the solutions, &c., &c. Similar results have been obtained in measuring the reaction between barium chloride and potassium oxalate in dilute solutions.

But however a special chemical decomposition may be influenced by such physical conditions as those mentioned, or by such physical conditions as temperature, time, &c., it seems very probable that each chemical molecule is possessed of a definite coefficient of affinity. The researches of Guldberg and Waage, as also those of Ostwald favour this view.

The law of mass action formulated by the former naturalists does not permit of determinations being made of the coefficient of affinity of any substance, but only of the ratio between the coefficients of two substances. Ostwald also does not attempt to do more than determine the *relative affinities* of substances.

He confines himself especially to the neutralisation of acids by bases; from his results he deduces the probable conclusion that the relative affinity of an acid is a fixed number independent of the nature of the base acted upon, and independent of temperature. The relative affinity is, however, a function of the absolute affinity which is itself

probably influenced by temperature, pressure, and nature of the base neutralised. Ostwald's researches show that the affinity exerted between an acid and a base may be regarded as the product of the specific affinity-constants of the acid and of the base; *i.e.*, as made up of two parts, one of which is dependent on the acid and the other on the base.

The connection between chemical structure and affinity is touched upon by Ostwald. His numbers show that while the relative affinity of acetic acid is represented by about 1·3 (nitric acid = 100), that of monochloracetic acid is represented by 7, that of dichloracetic acid by 33, and that of trichloracetic acid by 80. Similarly, the entrance of oxygen into the molecule of an acid increases the affinity, while the addition of CH_2 decreases the affinity.[1]

The importance of the results, a very short sketch of which I have endeavoured to give, cannot be overlooked. We seem approaching the time when exact knowledge will be obtained of that mysterious force, chemical affinity; but before this exact knowledge is attained, much work remains to be done. Not the least of the benefits bestowed upon their fellow chemists by the three naturalists whose papers I have mentioned, is that they have directed their attention to a branch of chemical science which, although it presents great difficulties, yet promises results of the most paramount importance to science.

Cambridge, August M. M. PATTISON MUIR

[1] The results of Ostwald, and also those of Guldberg and Waage, are corroborative of those obtained by Dr. C. R. A. Wright in a paper published in the *Phil. Mag.*, December, 1874.

NOTES FROM ICELAND

DURING the last three weeks the writer has travelled over between four and five hundred miles of country in Iceland, in the course of which various facts have presented themselves which may interest some of the readers of this journal. These "Notes" are necessarily desultory, because the main facts connected with the natural phenomena of the country are so well known that the most we can do is to supplement some of them.

Submarine Eruption off Cape Reykjanes.—The only eruption recorded in Iceland during the present year took place off Cape Reykjanes on May 30, near the Geirfuglasker island, thirty-two miles from land. It is described by a farmer named Guðmundsson, living near Kirkjuvogr, and his account of it is published in the *Heilbrigdistindi* for June last. Smoke appeared from the sea on May 30, and on June 1 it was carried inland by a west wind. For thirteen or fourteen days it was difficult to navigate the sea about Reykjanes on account of the smoke, and just before it cleared off, ashes fell on the coast lands. An appearance as of fire was also seen out at sea. This is positively all the information we possess concerning this eruption. It is sufficiently meagre, but the district about Cape Reykjanes is very thinly populated. The road, or track, is carried over a lava-stream, and is one of the worst in Iceland; the houses are few and far between, and the keeper of the lighthouse told us we were the only visitor he had seen this year. It is probable that volcanic phenomena often pass unnoticed in a country which is so thinly peopled, that with an area one-sixth larger than that of Ireland, the population (72,000) is less than that of Norwich. Submarine eruptions have more than once previously taken place in this district; small volcanic islands have been raised above the level of the sea, and have sunk again, leaving dangerous reefs. At Cape Reykjanes (hence the name) there are numerous hot springs which deposit silica, and which are therefore of the same nature as the geysirs. The springs rise through beds of highly decomposed tuff; large quantities of steam are emitted, and the soil in the vicinity is so soft that it is necessary to carefully choose one's footing. Pools of boiling blue mud (like the *maccalube* near Girgenti) are also found in the vicinity.

Craters of the Eruption of Hekla of February, 1878.—Last autumn we gave an account in this journal (vol. xviii. p. 596) of a visit to the scene of the new eruption, which took place about four miles from the principal craters of Hekla at the end of the preceding February. The observations of Herr Nielsens, a merchant of Eyrarbakki, and of Prof. Tomas Hallgrimson, were also recorded. The former has just communicated to the writer the result of certain measurements of the principal of the new craters, which he made a few months ago. Three of the craters in the centre of the group were measured. The form of the first is that of a funnel, 100 Danish feet[1] in diameter. A good deal of steam issued from the bottom of the crater, and prevented the depth from being accurately determined, but it appears to be about 150 feet. The second crater is of horseshoe form, the straight wall joining the curve of which, is perfectly vertical. The diameter increases as it descends, being at the top about 30 feet, and at the bottom 50; while the depth is also 50 feet. The third crater is of the shape of a parallelogram, 40 feet long by 30 broad, and 40 feet deep. The walls are perpendicular. No lava issued from the second and third of these craters, but quantities of ash and pumice. The greatest quantity of lava flowed from the most southerly crater nearest to the summit of Hekla. The approach to this is very difficult on account of the extreme jaggedness of the lava. The whole field of new lava appears to be covered with an innumerable quantity of small craters, but a closer examination proves that they have been produced by the molten lava beneath forcing out portions of the upper solidified crust, at places where snow or water caused the generation of large quantities of steam. Most of the real craters are split in twain, and the sides are lined with incrustations of common salt.

A few weeks ago Miss Thora Pjetursson, of Reykjavik, ascended Hekla, and reports the appearance of steam from one of the main craters; last year when we ascended the mountain no trace of steam appeared from any one of the three main craters, the most recent of which was formed in 1845. Hekla only enters into eruption at long intervals of time.

Slight shocks of earthquake are common in the south-east districts, in Guldbringu Sysla and Rangarvalla Sysla.

Climate.—The presence of jokulls covered with perpetual snow; of the Gulf Stream, and of an arctic current, tend to make the climate of Iceland very variable and subject to sudden changes. On August 20, when we left Kalmanstunga, in the centre of the island, the sun was as hot as during an English mid-August day; later in the day as we passed the Geitlands jokull a piercing icy wind bore down upon us with great force, and again towards evening when we entered the northern end of the Thingvellir valley it was warm and summer-like. During the course of that day we experienced a difference of more than 100° F. Again on August 30, at Eyrarbakki, on the south coast, N. lat. 63° 65′, the thermometer at 6 A.M. stood at $-1°$ R. = 29°·75 F., and a crust of ice had formed on all exposed water. At 10 A.M. a bright hot August sun was shining and the air was still. At 3 P.M. rain and violent wind occurred, and towards evening it again cleared up. Frequently the wind drops suddenly, and a complete change of weather may take place in the course of a few hours. The summer has been unusually dry and warm, but on August 31 the weather began to break up. On that day we travelled from Eyrarbakki to Reykjavik by way of Reykir (in Olfusahreppr), and we shall never forget the difficulties of crossing the Helliskard, a low spur of the mountain Hengill. The whole tract is either the living palagonite rock, or detached fragments heaped together in confusion. Hence it is only possible to proceed at a slow space. A violent wind

[1] One Danish foot = 1·125 English foot.

swept over the face of the mountain, driving the rain in almost horizontal sheets along the surface. From time to time mists floated over the mountain, and it was bitterly cold.

Iceland a Meteorological Station.—If Iceland were connected with the Faëroe Islands, and with the north of Scotland by telegraph, there can be no doubt that it would form a valuable meteorological station, although from the various disturbing influences the effect of which would be comparatively local, such as the jokulls and the various local currents, such a station would be less valuable than would be afforded by a vessel moored 600 or 800 miles out in the Atlantic between Ireland and Newfoundland, and in telegraphic communication with the central office in London.

Drift Wood of Iceland.—Great quantities of drift wood are thrown upon the southern coast of Iceland. It is said to be chiefly fir, and it is asserted by some to come from Siberia by an arctic current, and by others from America by the Gulf Stream. We noticed that the coast between Grindavik Staðr and Cape Reykjanes was far more thickly strewn with drift wood than the coast more to the east in the neighbourhood of Eyrarbakki. As the Gulf Stream impinges on the south-western peninsula, it would seem that it must therefore be the chief source of the drift wood. The trees that we saw were torn up by the roots, and they were completely blanched, and in many cases riddled with holes by some species of borer. A portion of the skeleton of a large whale was visible on the shore near Grindavik.

Improvements in Iceland.—During the year which has elapsed since we last visited Iceland, several very marked improvements have been set on foot. In no respect is this more conspicuous than in the case of the roads. A few years ago a writer made the assertion "there are no roads in Iceland." At the present time road-making is making great progress, and many scores of miles of excellent roads exist. Of course we mean such roads as alone are possible, without great expenditure of money and labour, in a country which is one vast volcano. Driving roads are impossible, but excellent pony roads are being constructed, and will greatly facilitate despatch of business and intercommunication. The first bridge in Iceland is about to be commenced. It will cross the Olfusà, and materially help to establish a better communication between the east and the west. A second bridge is to be thrown across the Thjorsa. The first lighthouse in the island was erected a year ago, and the light-dues paid by ships at the port of Reykjavik have already almost paid for its construction. There is some talk of founding a school of farming at Moðrudalr in the north-west, and a law school in Reykjavik, where a divinity school and a medical school already exist. In Reykjavik new houses are being built; there is a proposition on foot to build an hotel, and a new house for the Althing, which now holds its biennial meetings in the Latin school. Hafnafjord and Eyrarbakki are flourishing little ports; Akureyri does a fair trade in shark liver oil, and in ponies; and the Krisuvik sulphur mines appear to be in good working order, and to yield a rich product.

Reykjavik, September 2 G. F. RODWELL

ON HARMONIC RATIOS IN THE SPECTRA OF GASES

PROF. G. JOHNSTONE STONEY has given in the April number of the *Phil. Mag.* for 1871 some remarkable ratios of the wave-lengths of three of the hydrogen lines. Prof. Soret and Mr. Lecoq de Boisbaudran have also given several similar ratios, and I have found at various times a great many. It is, however, impossible to decide, without a thorough discussion, how many of these harmonic ratios may be due to accident. All possible fractions in a given spectrum ought to be calculated, and we could then see, by the theory of probability, whether the coincidences with ratios of comparatively small numbers are more numerous than we ought to expect. I began this work about a year ago. The calculation and discussion of twenty thousand fractions will necessarily take some time. The following simple ratios, however, which I have found in the iron-spectrum, I believe to be worth recording. I may say that I have gone only through the seventh part of that spectrum as yet. The first column in the following table contains the corrected wave-lengths of iron lines as given by Ångström. If these numbers are multiplied by the fractions given in the second column, we obtain the calculated values of other iron lines. The observed values and difference are given in the fourth and fifth columns.

λ	Fraction.	Calculated.	Observed.	Δ
6302·49	8 : 10	5041·99	5041·69	−0·30
6231·64	5 : 6	5193·03	5193·25	+0·21
6192·43	9 : 10	5573·19	5573·37	+0·18
	6 : 7	5307·80	5308·10	+0·30
6137·53	8 : 9	5455·58	5456·36	+0·72
	7 : 8	5370·34	5370·65	+0·31
6066·39	7 : 8	5308·09	5308·10	+0·01
6009·32	8 : 9	5341·62	5341·87	+0·25
	2 : 3	4006·2	4006·0	−0·2
6003·92	7 : 10	4202·74	4202·75	+0·01
	5 : 6	5003·27	5003·52	+0·25

The differences could of course be reduced to one-half by throwing part of them on the possible errors in the observation of the wave-lengths given in the first column. It is to be remarked that the intensities of the iron lines which figure in the above table are as a rule very strong. Thus all but three of the lines have an intensity of over six attached to them in Watts' Index.

The following table contains a set of iron lines, which can be arranged as harmonics of a fundamental vibration whose wave-length is 0·018694765 of a millimetre.

The table is arranged according to the pattern of that given by Prof. Stoney for the hydrogen lines.

Observed wave-lengths in vacuo.	Calculated values.	Differences.
6231·64	$\frac{1}{30} \times 186947·65 = 6231·59$	+ 0·05
5498·28	$\frac{1}{34} \times 186947·65 = 5498·46$	+ 0·18
5193·25	$\frac{1}{36} \times 186947·65 = 5192·99$	+ 0·26
5052·53	$\frac{1}{37} \times 186947·65 = 5052·64$	− 0·11
4919·63	$\frac{1}{38} \times 186947·65 = 4919·68$	− 0·05
4248·08	$\frac{1}{44} \times 186947·65 = 4248·81$	− 0·73
4064·1	$\frac{1}{46} \times 186947·65 = 4064·1$	− 0·0

I have included the forty-fourth harmonic, because Thalén gives 4248·8 for the observed value of the wave-length, which reduces the difference to zero. I must, of course, complete the investigation before I can definitely say in how far all these coincidences may be due to accident. On the whole, as far as I have hitherto gone, the result does not seem to be decisive in favour of such a simple connection between the wave lengths of different lines. The true law of the distribution has not yet, I believe, been found, but harmonic ratios may take a secondary part. ARTHUR SCHUSTER

OUR ASTRONOMICAL COLUMN

PALISA'S COMET.—The following elements of this comet have been calculated by Mr. Hind from the first Pola observation on August 21, one at Leipsic on August 28, and M. Henry's observation at Paris on September 11:—

Perihelion passage, 1879, October 4·2871 G.M.T.

Longitude of perihelion	201° 41′ 52″·8	Apparent Eq. August 31.
,, ascending node ...	86 54 4·2	
Inclination	76 57 38·2	
Log. perihelion distance	9·9983406	

Motion—direct.

Positions deduced from these elements for midnight at Greenwich are:—

	Right Ascension. h. m.	Declination North. ° ′	Log. distance from Earth.	Log. distance from Sun.
Oct. 2	14 19·1	22 31	0·2044	9·9985
3	— 23·5	21 30		
4	— 27·9	20 30	0·2072	9·9985
5	— 32·1	19 29		
6	— 36·3	18 28	0·2106	9·9987
7	— 40·4	17 28		
8	— 44·4	16 27	0·2144	9·9995
9	— 48·3	15 27		
10	— 52·2	14 28	0·2187	0·0008
11	— 55·9	13 28		
12	14 59·6	12 30	0·2234	0·0027

On November 4·5 the right ascension is 242° 40′ and the declination 7° 6′ south, the comet setting in London two and a quarter hours after the sun; the intensity of light is then somewhat greater than at discovery, so that observations may be expected till about a month after the perihelion passage.

NEAR APPROACH OF COMETS TO THE EARTH.—Amongst the cases of close approach of comets to our globe there are two in which we are able to fix the actual degree of approximation with certainty, the orbits at the times having been determined with great precision. The first is that of the comet of 1770, treated of by Laplace in the *Mécanique Céleste*. According to Clausen's elaborate investigation, in which the effect of the earth's attraction is included, this comet at 5h. 6m. P.M. Greenwich time on July 1, was distant only 0·01509 of the earth's mean distance from the sun, or 1,390,000 miles, and it is the closest approach of one of these bodies of which we have any certain knowledge. On this evening its apparent diameter, as measured by Messier, was no less than 2½°, or nearly five times the apparent diameter of the moon; at this time the comet was traversing the constellation Draco. The second case is that of Biela's comet at its appearance in 1805. At 9h. P.M. on December 9, just before it descended below the horizon in Europe, and almost at the time of the last observation by Thulis at Marseilles, the comet was distant 0·0366, or about 3,380,000 miles. There can be little doubt that the comets of 568, 1366, 1472, and others passed near the earth, but the elements of their orbits are not determinable within anything like close limits. The first comet of 1743, for which Clausen assigned an elliptical object, was also near to us, but the orbit in this instance is doubtful, and the actual distance in perigee cannot be deduced with precision.

There have been many instances where comets at one or other node have passed much nearer to the *earth's orbit* even than in the case of the comet of 1770, as occurred with Biela's comet in 1839, but the nodal passages have taken place when the earth has been far removed from these points of her path.

BIOLOGICAL NOTES

THE "CHALLENGER" RHIZOPODS.—In the current number of the *Quarterly Journal of Microscopical Science* Mr. H. B. Brady, F.R.S., continues his very interesting preliminary report on the porcellanous and hyaline types of rhizopods met with in the dredged stuff brought home by the *Challenger* Expedition. He very justly abolishes the misleading generic names of *Tri-* and *Quinque-loculina*, agreeing with Prof. Williamson to employ the modified term *Miliolina* for the section. Quoting *Decaisnella*, M-Chalmas, as a synonym of *Dactylopora*, P. and J., he mentions that *D. eruca* occurs in considerable variety of form, but that after the examination of a large number of fresh specimens, he has never seen anything to correspond to the structures figured in M-Chalmas's paper in the *Comptes Rendus*—figures curiously enough reproduced in another portion of the same journal, in which Mr. Brady's paper appears. The species of *Lagena* found supply material, we are told, for five or six crowded plates, its varieties embracing modifications of contour and surface decoration before unknown and most remarkable for their individual beauty. The rare and interesting *Pavonina flabelliformis*, D'Orbig., has been taken at three of the *Challenger* stations; originally described imperfectly by D'Orbigny from a specimen from Madagascar in 1826, it remained unknown until dredged by Dr. E. Perceval Wright in shallow water near the Seychelles. Two excellent figures of it are given. A number of forms of *Globigerina* are described. *Hastigerina*, Wy. T., is referred to *Nonionina*, D'Orbig. The paper closes with some notes on "Pelagic Foraminifera," in which, "while without departing from an attitude of caution in accepting evidence upon a subject so beset with difficulties," the author confesses that he sees no anomaly in the supposition that organisms so simply constituted as this group of protozoa may be equally at home at the surface and at the bottom of the ocean.

THE "CHALLENGER" ECHINI.—Prof. Alexander Agassiz has just published a preliminary report on the echini of the exploring expedition of H.M.S. *Challenger* in the *Proceedings* of the American Academy (vol. xiv. p. 190, June, 1879). It was not Agassiz's intention to publish this preliminary notice, as he hoped to be able to issue the descriptions of the species with his final report on the group; he found himself, however, compelled for the sake of retaining for the material of the *Challenger* expedition the priority of discovery, to notice, however briefly, the magnificent collection of sea-urchins intrusted to his care by Sir Wyville Thomson. In contrasting this collection with those made during the two expeditions of the U.S. steamer *Blake*, Agassiz says that these latter contain some of the most interesting forms obtained by the former, often complementing more or less imperfect *Challenger* material. Among the Cidaridæ, Arbæciadæ, and Diadematidæ, many new species were found, and a new genus allied to Astropyga. Among the Echinothuriæ, a number of new species were dredged. Among the Echinometradæ nothing of importance was collected. Among the Temnopleuridæ excellent series of the species of Salmacis and Temnopleurus were obtained, a Cottaldia, hitherto only known from the chalk, and an exquisite genus Prionechinus, allied to Salmacis. The most interesting feature of the Echinidæ proper, was the occurrence of several northern forms in deep water in the tropics. Not a single new species of Clypeastroids was found, and the number of specimens even was quite small. They do not play any important part in shaping the character of the fauna of deep water, and are, perhaps, the most strictly littoral group of Echini, indicative at least, in the present epoch of comparatively shallow water, inside of the 100-fathom line, and probably giving us a good guide as to the depth of the sea and the nature of the bottom of the cretaceous and tertiary shores, where they occur in such large numbers. One recent species of Catopygus is interesting, as adding another of the cretaceous forms to those still living. By far the most interesting group of Echini is that of the Pourtalesiæ—the species were found in abundance; of Pourtalesia there are six species. In Cystechinus there are three species, *C. Wyvillii* and *C. clypeatus* have quite stout tests, while in *C. vesica* the test is reduced to a mere film, so that even in alcohol the shape of this sea urchin reminds one of the crown of an old felt hat which had seen its best days. The test of all the Pourtalesiæ is quite delicate, the amount of lime-

stone being, at the great depths where they occur, reduced to a minimum, and yet even at the greatest depths they are found associated with Ophiurans, which are by no means wanting in lime. Among the Euspatangia, *Spatangus purpureus* occurred in the tropics at a depth of 400 fathoms, and *Echinocardium australe* was dredged at the great depth of 2,675 fathoms. In Australia it is a littoral zone species. Among the Brissina two species of Hemiaster were obtained allied to *H. prunella*, a new species of Rhinobrissus, and two new ones of Schizaster. No better idea can be given of the value of this extraordinary collection than by stating that there are described in this list no less than forty-four new species. At the time of the publication of Agassiz's "Revision of the Echini," there were scarcely over two hundred species of Echini known, and since that time less than fifty species have been added to the list. In the specific diagnosis of the species only the principal localities are given; the full details are reserved for the full report, which we believe is in good progress, many of the requisite illustrations being already engraved.

ATLANTIC STALK-EYED CRUSTACEANS.—Mr. S. J. Smith, of Yale College, publishes, in the *Transactions* of the Connecticut Academy of Arts and Sciences (vol. v. part 1), an account of the stalk-eyed crustaceans of the Atlantic Coast of North America. This account forms part of the report in preparation for the United States Commissioner of Fisheries. It embodies the study of the extensive collections made during the past fourteen years by Prof. Verrill and himself. In the present paper only the species inhabiting the coast between Cape Cod and Northern Labrador are given, and although the paper has special reference to the geographical distribution of the species, considerable matter is introduced in regard to specific variation and specific characters, and under some of the species, to the synonymy, especially where it seemed necessary to the proper understanding of the geographical distribution, or to show the propriety of the nomenclature adopted, or where the species is not well known. The total number of species recorded is 73, of which 45 are Decapods, 11 Schizopods, and 17 Cumaceæ, one-half of which are also to be found in Europe, the author concluding that there is not only a close relationship between the marine fauna of Greenland and that of Northern Europe, but a similar close one between that of Greenland and of the coasts of the continent of North America.

LAND-SHELLS OF CALIFORNIAN AND MEXICAN ISLANDS.—In a short paper in *Proc.* Acad. Nat. Sci. of Philadelphia for 1879 (p. 16), Mr. W. G. Binney gives an important contribution to the geographical distribution of land-shells. The Mexican island of Guadelupe, 220 miles from San Diego, off the west coast of Lower California, has been visited by Dr. E. Palmer, and he found numerous fragments of snail-shells which had been devoured by a species of mouse, the only land mammal on the island. These appeared to belong to *Arionta rowelli* (Newcomb), found in Lower California. *A. facta* occurred, a variety with open umbilicus, like that found fossil on San Nicolas Island, California. Living specimens of *Binneya notabilis* were brought from Guadelupe, found also on the Californian island of Santa Barbara; it is very nearly allied to if not synonymous with the Mexican genus *Xanthonyx*. Thus it is supposed to have been first distributed from Mexico, then to Guadelupe, thence to Santa Barbara.

NEW GENUS OF FISHES APPROXIMATING TO THE MACKEREL.—In the San Francisco market a fish is often exposed for sale, having a long body, with more than seven finlets behind dorsal and anal fins, the body having long narrow scales on region behind the eye, on each side of the dorsal outline, and on base of tail; the rest of the body is bare of scales. It has no corselet, and no teeth on vomer or palatines. There are fifteen dorsal spines, very fragile and slender. The ventral fins are very small, the colour is dark steel blue above, silvery below; and there are no streaks. The length of a specimen described by Mr. Lockington (*Proc.* Acad. Nat. Sci. Philadelphia, 1879, p. 136) was 21 inches to end of middle rays of caudal, length of head $4\frac{1}{4}$ inches, greatest depth of body $4\frac{1}{8}$ inches, length of pectoral fins $2\frac{5}{8}$ inches, ventrals 1 inch.

HAIR-WORMS.—Curious knotted masses of hair-worms (Gorduis) are sometimes found in gutters after rain. Prof. Leidy disentangled one such mass last winter, containing fifty-two males and seven females; the former were from 8 to 25 centimetres long, and from one-half to two-thirds of a millimetre in thickness; the latter from 14 to about 20 centimetres long and 1 millimetre thick. These worms are very lively; and when disentangled soon become again aggregated with the heads external and divergent.

PROF. MARSH, when examining recently the Rocky Mountain deposits known as the Atlantosaurus Beds, was rewarded by the discovery of the lower jaw of a mammal, a diminutive marsupial (somewhat smaller than a weasel), differing widely from any living type. The remarkable feature in the jaw is the series of premolar and molar teeth. The nearest affinities of this mammal are with the genus *Stylodon*, of Owen, from the Purbeck beds of England. Prof. Marsh designates the new genus *Stylacodon*, and the species represented *S. gracilis*.

GEOGRAPHICAL NOTES

AT the meetings of the International Geodetic Association at Geneva the representatives of the various countries present reported on the works executed by their governments. We are pleased to learn of a resolution of the French Ministry to proceed to a new levelling of precision of the first order on a length of 17,000 kilometres; a levelling of the second order will follow on a length of 800,000 kilometres. The operations to connect Spain and Algeria, to which we have referred were also described. The next meeting will be held at Munich in the autumn of 1880.

A TELEGRAM from Samarkand to the Russian papers, informs us that the expedition for the tracing of a railway from Karaturghel to Tashkend and Samarkand has finished its explorations. It has explored the banks of the Syr-daria in the neighbourhoods of Kara-Uzyak, the coal-mines at Khojent, and the moving sands of Fergana, as well as a part of the Surkhan river and the roads from Samarkand through Djam-Karshee and Kitab-Shaar to the Iron Gate, and thence to the ruins of Termez on the Amu-daria. Throughout its route the expedition has made astronomical, meteorological, geological, botanical, and zoological researches; now it is engaged in a hydrographical description of the Amu-daria and of its delta.

THE Russian Government are actively pursuing the exploration of the great rivers of Russia in Europe. Thus, during the last three years the Volga was surveyed on a length of 775 miles; a thorough levelling is completed on 300 miles, and no less than 91,720 soundings give the necessary data for preparing a detailed map of the river. The Chussovaya river, one of the upper branches of the Kama river, has been explored on 270 miles, and the Byelaya, the other branch, on 160 miles. The Vyatka river is thoroughly surveyed and levelled. The description of the Vistula is quite completed. Extensive surveys and levellings were made on the river systems of the Dneiper and Bug, as well as on the Don, which is surveyed on a length of 560 miles. New surveys were undertaken last year on the Northern Drina and Sukhona, as well as in the basins of the Obi and Yenissei. Several stations were established for

observations on the changes of levels of rivers, as well as for meteorological observations and for weather-warnings.

THE official Report on the Forests in the South and West of the Island of Cyprus, by Mr. A. E. Wild, of the Indian Forest Department, goes far to explain the unhealthy climatic conditions now existing in the island, and of which so much was recently said. In the region named the forests are now mostly confined to the chain of hills running east and west, and even there the more dense and better growth is confined to the more inaccessible spots of the higher ranges. Round the villages and in suitable localities for transport the forest is already so thinned as to be unworthy of the name. This unfortunate state of things, which has had a serious effect on the climate, has been brought about by the most reckless improvidence in the felling of trees, aided by fires and the ruinous mode of extracting resin. Mr. Wild appears to be of opinion that by a careful system of forest preservation, which need not involve us in a large expenditure of money, the damage caused under the Lusignan and Turkish rule, may be to a material extent repaired in the course of fifty or sixty years.

M. E. F. BERLIOUX, Professor of Geography at Lyons, has just issued a second edition, revised and enlarged, of his *brochure*, entitled "Les Anciennes Explorations et les Futures Decouvertes de l'Afrique Centrale," which is illustrated with a curious map of the northern portion of the continent.

A PARTY of forty-seven persons, amongst whom there are twelve married couples, and fourteen children, sailed last week from Bergen (Norway), with the intention of colonising the Aldabra Islands in the Indian Ocean (in about 9° lat. S. and 46° long. E.). The idea resulting in this undertaking was first conceived by two Norwegians, who had repeatedly visited Madagascar, where they had learnt that the Aldabra Islands are uninhabited at present, and excellently adapted for colonisation.

MUCH attention is just now being attracted in Queensland to the proposed scheme for a Transcontinental railway to Port Darwin on the northern coast, of the suggested route for which a flying survey has recently been made by Mr. Faveuc and a party who started from Blackall, in Queensland. The present idea is to commence the line at Roma on the existing system, whence it would be taken by way of Blackall to the South Australian frontier, a distance of 750 miles. From that point it would still follow a north-westerly direction to Port Darwin.

A MEMBER of the Japanese mission now at the capital of Corea writes to the *Osaka Nippo* that the new ports, which it is proposed to open in that country, are Jin-sen, in Kei-ki-dō, and Gen-san, in Kan-kiyo-dō, the former of which is only eight *ri* distant from the capital. A Japanese surveying officer has also been engaged in making investigations at the port of Dai-on, in Kei-ki-dō, about eighteen *ri* from the capital, along the road to which there are many royal tombs. Partly on this account, and also because the road is considered a very important one, the Coreans for some time obstinately refused to permit the surveying officer to travel over it; eventually, however, they gave way. Great benefit, it is thought, would accrue to commerce if this overland route were opened. The Corean capital numbers among its residents many nobles and wealthy men, and several of the latter, who hold progressive ideas, are said to have ordered European articles at the open port of Fusan in the south. When the port of Jin-sen comes to be opened, it is believed that foreign merchandise will be in great demand.

OFFICIAL statistics respecting the population of Netherlands India at the end of 1876 have lately been issued, from which it appears that exclusive of the army, there were then in Java and Madura 18,515,414 people, being an increase of about 170,000 over the previous year. The natives figure for 18,278,998, of whom 8,921,348 were males, while the remainder is made up of Europeans, Chinese, Arabs, and other foreign Orientals, the Celestials being, of course, in a large majority. This remark also applies to the other possessions in Netherlands India, including Sumatra, Celebes, &c. Owing to the incompleteness of the returns of natives in these islands, no estimate of their total population can be arrived at.

WILLIAM WILSON SAUNDERS

WILLIAM WILSON SAUNDERS, F.R.S., F.L.S., &c., who, as we stated last week, died on September 13, was born June 4, 1809, the son of the Rev. James Saunders, Vicar of Kirtlington. He was educated at Addiscombe, and went to India as an engineer officer in the Hon. East India Company's service. While there he published his first scientific paper, in *Gleanings in Science* "On Hydraulic Cements," in 1831, and also devoted a great part of his leisure to the study of plants and insects, and made collections, which he brought back with him in 1832. Having left the service, he settled at Wandsworth, and shortly after joined his father-in-law in business at Lloyds, still continuing his natural history studies. He was one of the original members of the Entomological Society, and read his first paper, "On the Habits of some Indian Insects," in April, 1834. This was followed by many others, mostly of a descriptive nature. He was President of the Society in 1841, 1856, and 1857, and many times served as vice-president. He was also elected a Fellow of the Linnean Society in 1833, and was vice-president from 1856 to 1874, and treasurer from 1861 to 1873. He became a Fellow of the Royal Society in 1853, and was also a Fellow of the Zoological Society and Royal Horticultural Society, and on the Council of the latter he took an active part. His natural history collections gradually increased in extent from the time of his return from India, and he devoted himself principally while at Wandsworth to horticulture and entomology and to the formation of an extensive herbarium and collection of woods, with notes of the density and weight per cubic foot of each, which latter was exhibited at the great Exhibition of 1851. The Report of the Juries for the Exhibition gives a classified catalogue of them, with remarks as to their uses, &c.

In 1857 he went to reside at Hallfield, Reigate, and removed there his various collections, largely extending them, and adding collections of birds, shells, vegetable products, &c. His attention, however, was always mainly given to horticulture and entomology, and especially to the study and cultivation of the aloes, Crassulaceæ, Cacti, and other succulent plants which could not be duly studied in an herbarium, and to the smaller and more obscure species of orchids; and it was to bring these interesting and curious plants more prominently before the botanical world that he resolved on the publication of the "Refugium Botanicum," the first number of which appeared in April, 1868. In this work he had the valuable assistance of Prof. H. G. Reichenbach for the descriptions of the orchids, and of Mr. J. G. Baker, of Kew, for the other families, the plates being chiefly from the drawings of the well-known botanical artist Mr. Fitch, although some were from drawings of his own. The Fungi also attracted a good deal of his attention, and he made a series of very accurate drawings of all he was able to obtain, some of which have been reproduced in the "Mycological Illustrations," edited by him with the assistance of Mr. Worthington G. Smyth and Mr. A. W. Bennett; the first part of this appeared in 1871. Unfortunately neither the "Refugium" nor the "Mycological Illustrations" have ever been completed.

His entomological collection included insects of all orders, and though perhaps he gave more special attention to the Lepidoptera and Coleoptera, he was always

anxious to get together all the curious and striking forms he could, and his collections of Orthoptera, Hymenoptera, and Hemiptera were probably among the most extensive known.

Throughout his life he made copious notes and drawings of any natural curiosities that came under his notice, and kept a regular record of the rainfall and other meteorological occurrences. The care of all his collections, &c., occupied so much of his time that he had little left to devote to literary work, but he always allowed free access to the collections to any who were working and might benefit from them. At Reigate he started the Reigate Natural History Club, of which he was president for many years, and which still flourishes.

He left Reigate on account of business difficulties in 1873, and his collections were sold and dispersed. He then went to Worthing, where he resided till his death, having again surrounded himself with all the interesting plants, insects, &c., that he could get together.

TAILS[1]

II.

ANOTHER animal, the tail of which is remarkable for its mass of hairy covering, is the great ant-eater. But much more renowned is the yak, the tail of which animal is carried before dignitaries in Central Asia as an ensign of honour.

Such, then, are some of the main peculiarities of the tail in beasts. It is generally long, but may be absent altogether. It is generally hairy, sometimes very hairy, but it may be naked. It attains a prodigious size in exclusively aquatic forms, and in less aquatic forms—like the otter—it is largely developed, and somewhat flattened laterally, to aid the body in swimming.

Let us now consider the tail of a bird, and contrast it with that of a beast.

Every one knows that many birds are spoken of as having long tails, and so they have, in a sense. But a glance at the skeleton shows that it is not in the *same sense* that a bird and a beast are said to be "long-tailed." The bones of a bird's tail are few in number, and short, so that the tail is always very short as regards its bony portion, and also as regards the muscle and skin which covers it. At its end is a more or less conical or "ploughshare-shaped" bone, made of several vertebræ, which have coalesced together. Into the skin, which invests this short tail, are set the more or less long tail feathers, which form what we ordinarily call "the tail" of a bird. On the upper surface of the fleshy tail birds also carry a sort of natural pomatum-pot. It is a grease-secreting gland, especially developed in water-birds, which may constantly be observed rubbing their bills first upon this region and afterwards over the feathers of their body, in order to give them a coating of this natural unguent. It is the presence of a good supply of this coating which renders the feathers of aquatic birds so impervious to water as to cause it to be thrown off with a readiness which has given rise to the familiar saying "like water off a duck's back."

All birds without exception which now live, have but a short tail—in the true sense of the word—however long may be the *feathers* which clothe that tail. But it was not always so. A very ancient fossil bird has been (a few years ago) discovered in the Solenhofen slate of Germany. This fossil proves that in the secondary period, birds existed quite like our present birds in general appearance, and in the main details of their structure, but with a tail formed of a number of vertebræ of considerable length, like the tail-vertebræ of a long-tailed beast or (as we shall see) lizard. On each side of this tail were set feathers, so that altogether the structure was like nothing which is to be seen in the world about us to-day.

[1] A Davis lecture recently delivered at the Zoological Gardens by Prof. St. George Mivart, F.R.S., V.P.Z.S. Continued from p. 512.

This bird was the renowned *Archeopteryx.*

FIG. 5.—The Archeopteryx (of the Oolite strata).

But apart from such old-world wonders as this, what we call a bird's "tail"—meaning thereby the long feathers of the hinder part of its body—does not always denote really the same part.

The true "tail" of a bird (in this sense) means the collection of more or less strong and more or less elongated feathers which are implanted into the skin investing its short bony tail.

Of this nature is the tail of an eagle, of an ostrich, and the longest of all such tails—the enormous tail of the beautiful Reeve's pheasant. You will naturally wonder why I do not include that most wonderful and magnificent object, the "tail" of a peacock. I do not include it for the simple reason that this so-called "tail" is not a tail. Not a "tail" in the sense of a beast's tail, or that of the archeopteryx; not a "tail" in the sense of an ordinary bird's tail, *i.e.*, it is not made of feathers implanted into the short fleshy tail.

The feathers of birds are classed by ornithologists in different groups according to their position on the body, and to each such group is given its own special name. Thus the long feathers implanted into the side of the arm and hand (by which long feathers birds fly) are called naturally "wing-feathers," but there are other feathers implanted in the body at the root of the arm, and which so lie that they cover over and protect the roots of the wing-feathers. These root, or covering, feathers, which are comparatively short feathers, are called *wing-coverts.* Just in the same way, there are ordinarily short feathers implanted in the hinder part of the body, which short feathers cover and protect the roots of the tail feathers. They are therefore called *tail-coverts.*

Now the magnificent plumes of the peacock are not tail feathers, they are *tail coverts*, enormously enlarged and greatly exceeding in size the true tail feathers.

You may have observed a peacock setting up its so-called tail; if not, take the next opportunity of observing it. You will see that these very long and delicate plumes are lifted up and sustained by means of certain short and stiff feathers, and if you get behind the animal, you will see these latter feathers, which can be erected and so prop up and support the great mass of long, radiating tail-coverts. These short, rigid feathers are the true tail feathers, and thus in truth the peacock has a short tail, not only as regards the skeleton, but also as regards the true tail-feathers, in spite of the length of that magnificent appendage which usage will force us still to call the peacock's "tail," even after we have made acquaintance with its real nature. Indeed it would be a piece of pedantry to call it anything else; but yet we may bear in mind, when we do call it tail, that we do not here denote by that word the same structure as we denote when we speak of the "tail" of ordinary birds.

This condition is not peculiar to the peacock, though it is the most striking instance of it. In such kinds as the grouse the tail is in large part formed by tail-coverts.

The "tail" of the lyre bird, on the other hand (the "lyre" being formed by the external thick and gracefully curved feathers, with delicate string-like feathers between) is a true tail, and its feathers are implanted around its bony tail.

It may be mentioned in passing that we sometimes meet with an analogous elongation of feathers of other parts of the body which are usually short. The beautiful and delicate plumes of the ordinary birds of paradise—those "crows" of Eden, for they are only kinds of crows after all—are made of exceedingly elongated axillary feathers, which in length greatly exceed the wings themselves.

To return, however, from wings to tails: the tails of birds, whether long or short, or whatever their nature, never serve the purpose which the tail serves in many beasts, and which we shall hereafter find reason to think was the very original purpose of "tails" when they first came into the world.

No bird swims by its tail. Birds, such as swans and ducks, swim by the paddling action of their feet. The most aquatic of all birds, the penguins, swim by the strokes of their wings, clothed with scale-like feathers—for the penguins may be said to fly under water. Whether any ancient aquatic bird once existed with a long tail like the archeopteryx is doubtful, but if it did, it is hardly likely that such an organ acted as a swimming organ. For to be able so to act, it must have been muscular, and therefore both thick and heavy, and therefore a fatal encumbrance to a creature destined for flight. If it were so furnished, and was destined never to fly, but to paddle like a penguin, in addition to propelling itself by lateral or vertical blows of a long and thick tail, then such a bird would be one difficult indeed for us to picture to our imaginations—though of course not outside the bounds of possible existence.

Let us now pass from considering the tails of birds, to a review of the tails of reptiles. In this matter we find a return to conditions we have made acquaintance with in beasts.

All living birds have tails which, as regards their bones, flesh, and skin, are nearly alike, but reptiles (like beasts) may have tails which are either long or short, according to their kind. We also here again meet with a "prehensile tail" like that of the kinkajou, or spider monkey. We find such a prehensile tail in the chameleon.

The chameleon is a creature destined to live on trees, and has its hands and feet modified into so many two-pronged grasping organs, to take a sure hold of the twigs and branches. It is a very slow animal, exceedingly deliberate in its motions, and did its hold partly fail, it would be incapable of rapid and sudden movements to save itself from falling, by a sudden clutch at some new point of support. Accordingly, it has an extra chance given it by its tail, which, tightly grasping by its curled end, gives the animal the advantage of what is practically a fifth limb.

Strange to say, though, it is not quite every kind of chameleon thus provided. There are many known kinds, and all but one have prehensile tails. One kind, however, not long ago described by Dr. Günther in the *Proceedings* of the Zoological Society, has a short tail, altogether destitute of any power of grasping. The tail, therefore, is useless to it as a prehensile organ, but instead it has, by way of compensation, serrated claws, which other chameleons have not.

The tail of the crocodile is a prodigiously powerful and very long one. It is thick, containing voluminous muscles, by the action of which this animal not only swims with facility, but when on land is able to deal terrible blows. Indeed lizards, with tails which are slender in comparison with the crocodile's tail, are yet able to deal powerful blows and to inflict whip-like cuts by means of lashing their long, rough-skinned tails. I am again indebted to Mr. Bartlett, for a note on this subject. He tells me that he found the large lizard called the Egyptian Monitor do this when lively and in full condition.

Most of my male hearers have, no doubt, when attempting to catch by their tails one of our little English lizards, been surprised to find the animal run away, leaving its tail behind in their grasp, and seeming none the worse for its sudden loss. The tail left behind will twitch and move about in a lively manner for a considerable time, especially on a very hot and sunny day.

This loss, which the animal so readily undergoes, is not, however, a permanent one. A new tail soon begins to sprout, and before very long an ordinary observer could not tell this new tail from the old one, although in the details of its structure it is not quite the same. The power of repair in these animals' tails may be shown in other ways. If the tail happen to be divided not transversely, but longitudinally, each such half will become an entire tail, when the process of reparation is complete; then, if each of the new tails be again longitudinally divided, each such new division will again become entire, and the process has been repeated till the lizard operated on came to have as many as sixteen tails, side by side.

The tails of lizards are most various in shape, although mostly long, and sometimes exceedingly so; there are what are called "stump-tailed lizards," as in the adjoining house at this moment. Some Australian lizards have short and flattened-out tails of exceedingly odd appearance, the utility of which it is hard to conjecture.

Snakes may, in spite of their always long bodies, have short tails, while in some kinds the tail is exceedingly long.

I have in this bottle a real "sea-serpent." Do not imagine, however, that it is the young of the renowned animal of our newspaper correspondents. That animal, if really any one animal at all serves as the foundation for these travellers' tales, cannot be a serpent. This creature, however, is a true sea-serpent—and a poisonous one to boot—and many such of various species are found in the waters of the Indian Ocean.

They exhibit a remarkable adaptation to their aquatic life, in that their tails are flattened laterally so as to fit them the better to serve as swimming organs, like the tails of fishes.

Some small serpents which burrow in the ground (*Typhlops*), and some legless lizards (*Amphisbæna*) of similar habits, have very short tails, while the two extremities of the body become strangely alike in appearance.

Other small burrowing serpents have the tail ending in a flattened disk, just for all the world as if a portion of it had been cleanly cut off and had then skinned over. The use of this structure is problematical.

My friend Dr. Günther writes to me on this subject:—"I have often thought of the use of the rough tail of the *Uropeltidæ*, and believe that it is used either for burrowing in the soil during a backward motion of the animal (like the roughness on the shell of some burrowing mollusks); or for affording to the animal, whilst it is burrowing in a forward direction, a firm support on the smooth surface of its burrow. It may be of use in both ways."

Most renowned of all serpents' tails, and justly so, is the tail of the rattlesnake. This organ consists of a thickening of the outermost skin (or *epidermis*) which invests the end part of the tail. The thickening takes the form of a series of rings, which encircle the tail, and of course diminish in size as they approach the tail's end. By a rapid vibration of the tail these thickened rings of horny substance (for epidermis has the nature of horn) strike one against another, and produce a very peculiar noise, which may occasionally be heard in our reptile-house, and is heard when the rattlesnake is alarmed or excited.

Thus the "rattle" of the poisonous rattlesnake (like the expanding hood of the poisonous cobra) must tend to act as a warning to creatures exposed to its attack. It is very difficult to see what service this rattling can do to the rattlesnake itself. It has indeed been suggested that the sound resembles running water, and that in this way

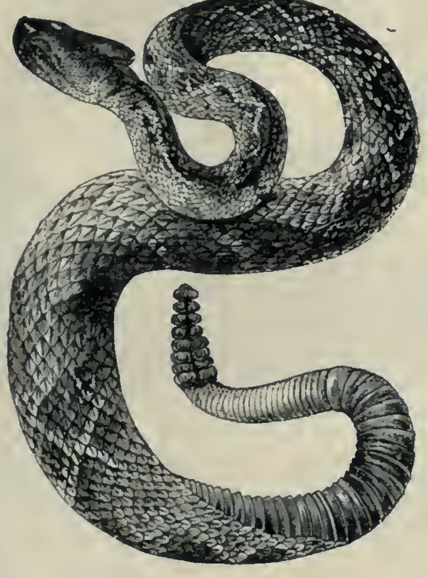

FIG. 6.—Tail of Rattlesnake.

creatures may be attracted to its vicinity. I must say that I for my own part have never been able to detect any such resemblance. Moreover, to have such an effect the rattling should be long-continued, whereas it is, in fact, kept up but for a short time, and is only produced at comparatively rare intervals.

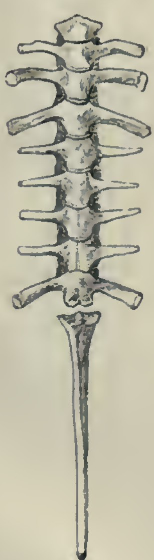

FIG. 7.—Backbone of the Frog (ventral aspect).

FIG. 8.—Backbone of the Frog (dorsal aspect).

Below the great group of reptiles is another group of animals, at one time associated with them, but now recognised as having a greater affinity with fishes. The group of animals I refer to is that which is made up of frogs and toads, together with efts (or newts), which latter are such familiar objects in our ponds in the spring of the year.

The efts have all long tails, but the frogs and toads are fully as destitute of a tail as we ourselves are, though they have a long slender bone at the hind end of their vertebral column, which bone reminds us of the ploughshare-shaped bone of birds. But you may recollect that this tail-less condition, even in ourselves, does not obtain in the very earliest stage of the human body. In frogs and toads a "tailed" condition endures much longer; for these animals, as you know, pass the first part of their life entirely in the water as "tadpoles," swimming about entirely by the undulating action of their long "tails." The tadpole is at first a singular object. It consists of a head and body indistinguishably united in one rounded ball, from behind which a long and slender tail projects. The creature may be said to be indeed at first "all head and tail," for its head is relatively very large, and the heart and other organs may almost be said to be included within it.

FIG. 9.—Tadpoles in different stages of development, from those just hatched (1) till the adult form is attained (8).

Whatever may be the best way, however, of regarding its head, there can be no doubt about its tail, its function, or its fate. It is, as I have said, a swimming-organ, but you know that as the tadpole becomes a frog or toad, it either comes on land or swims in quite another fashion from what it does as a tadpole, usually by striking out with its legs and feet, just as we swim, only it does it much better. Thus the tail becomes a superfluous appendage, and indeed as the limbs grow, the tail is gradually absorbed. It is not cast away! Our popular novelist was wrong in writing "What next! as the tadpole said when his tail dropped off;" it does not "drop off," but is sucked up by the creature's body gradually. Indeed the animal feeds upon its tail, not by turning round, biting, and eating it, but by its substance being gradually taken up and absorbed by the blood-vessels, and carried elsewhere, to assist the processes of bodily growth and development which are rapidly taking place.

Tadpoles and efts lead us naturally to the last and lowest class of backboned creatures the class of *Fishes*.

As these animals are all aquatic, so they all have more or less long and powerful tails. Almost always they swim by striking the water right and left with the tail, and as they breathe by gills, without coming to the surface, so the tail and its hinder end are flattened from side to side, and not from above downwards, as we have seen to be the case with the air-breathing whales and porpoises.

Some fishes, however, progress largely by means of great lateral fins, as is the case with the rays, or skates, and in them the tail is comparatively small.

There are certain fishes which go by the name of *Sea Horses*, though they are but small creatures. These fishes swim through the water in a remarkable way. They appear as if they glided at will without effort. But there is on the back a small fin, which by its constant undulations acts like the screw of a screw-steamer. It is by this the creature moves, and the long tail takes no part in such progression, and is relatively thin and small, except as to its length.

In this tail, however, we find once more that prehensile character, such as we saw in the chameleon, the kinkajou, and others. The sea-horse anchors itself by clinging with its tail round sea-weed, or some similar object, much as do the animals mentioned.

The tails of fishes are like those of beasts and reptiles, supported by an extension of the back-bone, and, as a rule, contain no body-cavity. But the mode in which the vertebral column ends varies in different fishes in a way worthy a passing mention.

In such a fish as the sturgeon the end of the tail is furnished with a fin, divided into two unequal lobes. The end of the vertebral column runs along in the upper lobe, but there is nothing similar in the lower lobe, so that the lobes of the tail are very unequal, not only in size, but also in structure. The tail-fins of sharks are similarly conditioned. In such a fish as the cod-fish, on the other hand, the vertebral column seems to stop short in the middle between the two lobes of the tail, which lobes are equally developed.

This difference may seem trivial, but, in fact, it is characteristic, not only of different groups of fishes, but of fishes of different geological periods. The unequal tail end is the more ancient, and has gradually given place to the other apparently quite symmetrical form. I say apparently, because, in fact, when the symmetrically formed tail is minutely examined, it turns out that even here, the end of the vertebral column is turned up, extending dorsally as in the sturgeon and sharks. But it is only a minute portion which is thus turned up. However, it *is* turned up, and very strongly so, and thus the curious fact of the upward inclination of the tail is seen to be a general character of fishes, whether their tail-fins are apparently symmetrical or not.

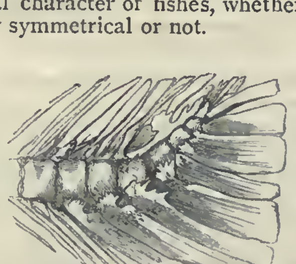

FIG. 10.—Post-axial termination of the vertebral column in a salmon.

Such are the main varieties of tail which are to be found in back-boned animals, that is to say, in beasts, birds, reptiles, frog-like creatures, and fishes; and thus we see that one general structure underlies the various varieties of external appearance which the tails of such creatures may present.

But there are many creatures of quite different nature and build, which are said to have "tails." Thus, for example, we speak of the "tail" of a lobster, or the "tail" of a scorpion.

Now, of course, I do not mean to assert here, any more than I asserted about the feathery so-called "tails" of birds, that you should depart from ordinary usage. Still, the so-called "tail" of such animals is really utterly unlike the tail of back-boned creatures, and is, in fact, but the backward prolongation of the body.

The lobster's body is made up of a series of more or less similar segments, in great part more or less agglutinated together. It contains a body-cavity which is traversed by the alimentary canal. The so-called "tail" does not differ from the lobster's body as the tail of a cat differs from the cat's body. For the tail of the lobster is also composed of a series of similar segments, also contains a body-cavity, and is also traversed for its whole length by the alimentary cavity—that is, by the intestine. The same is to be said with respect to the so-called "tail" of the scorpion, which, although so much more slender than the so-called tail of the lobster, is no more really a "tail" than is the latter.

We see, then, that the word tail in its proper signification means the prolongation backwards of a backbone (with the soft structures which surround it) beyond the body-cavity and behind the posterior end of the alimentary canal. This is the strictest meaning of the word "tail."

But other structures which, by their position, posterior extension, slenderness, or some other analogical resemblance, more or less resemble what is most properly and strictly called a tail, have the same term also applied to them.

While freely adopting popular usage in this matter, and calling, without scruple, by this term whatever is commonly and generally so termed, it is none the less well to bear in mind the differences which have been here pointed out as existing between the various more or less different structures which are thus spoken of by one common term.

The survey we have made has also another result. Different organs have not only their proper forms and structures, but also their proper uses.

The uses to which we have seen that tails are applied are more or less varied. Sometimes, indeed, the tail may serve as a fifth hand, as in the spider-monkey; but tails are generally related to locomotion, or at least to the balancing of the body, and prehensile tails are important aids to safe locomotion, especially in climbing.

But tails are most generally and largely developed in the class of fishes, and altogether the most effective aid to locomotion which tails offer is the aid they give in swimming. As, then, the essential structure of a tail is a backward prolongation of the vertebral column without any body-cavity, so the essential and fundamental *use* of a tail seems to be to act as a swimming organ. As the class of fishes seems to have been the first class of back-boned animals to come into existence, so we may deem it probable that a tail first appeared as a swimming organ added to a body in front of it, somewhat, perhaps, as we find the tail of our existing tadpoles.

This matter, however, is but one of speculation. But the world around us, as it exists now, affords us many examples of beautiful adaptation and utility in the structures in the examination of which we have been concerned to-day. The perfection of the hand, the varied adjustments of limbs, the wonderful complexity of the head, are matters for which every one would of course be fully prepared. But our survey may perhaps have sufficed to show that utility, beauty, and adaptation are exhibited to no small extent by organs the structures and functions of which are so rarely treated of and so slightly noticed as those with which we have been occupied, namely, the organs called "tails."

THE ALGERO-SPANISH TRIANGULATION

WE have received from Algeria further details as to the execution of the triangulation of the Algero-Spanish geodetic arc. The stations in the Algerian province of Oran are Msabia, a farm held by a colonist in the Mordzago at an altitude of 585 metres, and Mount Filhaoucen, at an altitude of 1,100 metres in Traras. These stations are at a distance of 108 kilometres from each other. The Spanish engineers have located themselves at Mulhacen, 3,500 metres altitude, in the Sierra Nevada, and Tetica, in the province of Murcia, 2,400 metres altitude. The distance from Tetica to Mulhacen is 88 kilometres. The two lines, Msabia-Tetica and Filhaoucen-Mulhacen, are respectively 270 and 300 kilometres long. In day-time signals were exchanged by sunlight and reflected by silvered glass mirrors 30 centimetres diameter; at night a Gramme electric machine was used in each station and worked by steam engine. The mirrors used for the electric light are 50 centimetres diameter. A telegraph line has been established from Oran to Msabia, a distance of 16 kilometres, so that Msabia is placed in direct communication with the European system. The temperature of the Spanish stations was very low, and fell several degrees under zero, while the heat was very great in the Algerian stations, which must be taken into account in the calculation of atmospheric refractions. Colonists and especially Arabs showed much surprise at seeing their mountains illuminated by a powerful ray of light which the French officers were sending from Filhaoucen and Msabia in the interval of operations. They were heard to say that the French had inherited the power of Allah, as they were making suns and stars.

THE IRON AND STEEL INSTITUTE

THE annual autumn or country meeting of this Association was held last week at Liverpool, in the concert room of St. George's Hall, the proceedings being opened with a few hearty words of welcome from the Mayor. The report of council showed that the Institution continued to flourish in spite of the hard times in the trade, fifty-eight new members having been added to the list on the last ballot and the proposal papers of thirty-eight received. The President then announced that the Council had accepted an invitation, numerously signed by representative firms in the iron trade of Westphalia to hold the autumn meeting of 1880 at Düsseldorf, which proposal was unanimously confirmed by the meeting.

After the completion of the formal business, the proceedings commenced with a discussion on the very useful method of determining manganese in iron ores, spiegel, ferromanganese, &c., by the volumetric method described by Mr. Pattinson, of Newcastle, at the last meeting in London, and which, according to the generally expressed opinion of chemists present, seems destined, for commercial purposes at any rate, to take the place of the more tedious analytical methods now in use.

Among the new communications prominence was given to a paper by M. A. Pourcel, of Terrenoire, on the causes of dephosphorisation of iron and steel, the principal idea in which was that the amount of phosphorus reduced from phosphates contained in iron ores depends mainly on the temperature and not on the reducing energy of the furnace temperature, instancing the fact that from the same ores pig-iron containing phosphorus in proportions varying from 1 to 3 might be obtained in the blast-furnace, according as the coke charge in the furnace was heavily burdened or not, a conclusion that did not find much favour among the members present.

A second paper on the neutralisation of phosphorus in iron and steel, by Mr. Richard Brown, of Ayr, proposed the addition of small doses of bichromate of potassium to the metal in the converter or melting furnace in order to introduce a small proportion of chromium into the finished steel. According to the author's statement, metal with from 1 to 1½ per cent. of phosphorus may be made to show fair working qualities, when containing 0·1 to 0·2 per cent. of chromium as a corrective, but from the results of the tests produced in support it appeared to be extremely irregular, as regards extension under strain. In the discussion on this paper some interesting remarks were made incidentally by Mr. Riley on the working of a chromiferous pig iron, which was made to some extent in Tasmania, and from which great things were expected, but it had been found impracticable to produce clean iron from it in the puddling furnace, owing to the refractory character imparted by the chromium to the slag. Another paper by Mr. Bull reproduced the old idea of dephosphorising by means of steam, but no very new facts appear to have been brought forward by the author. A useful method of compressing the tops of steel ingots by the direct action of high pressure on the surface of the molten metal, invented by Mr. H. R. Jones, of Pittsburg, Pennsylvania, was described by Mr. Davis. This appears to mark a real progress in the manipulation of the metal, as the proportion of unsound ingots is said to be notably reduced by its use. Of more general interest than the formal papers, however, was the statement made by Mr. Windsor Richards, on the progress achieved in the dephosphorising of Cleveland pig-iron in the Bessemer converter by the Thomas-Gilchrist-Snelus process since the last meeting, which Mr. Bell pronounced to be an absolute scientific success, steel rails produced by this method at Eston from Cleveland ore having satisfactorily passed the tests prescribed by the North-Eastern Railway Company. Several minor papers less intima ely connected with the main objects of the Institution, such as the use of glass toughened by Siemens's process of annealing for tramway sleepers, the progress of iron and steel as constructive materials were also read during the meeting. The afternoons, in accordance with the usual custom, were devoted to excursions, the members being fortunate enough to have the three finest examples of the Transatlantic steamers belonging to the Cunard, Inman, and White Star Lines in port and available for their inspection at the same time. The Warrington Wire Works, the largest manufactory of the class in the country, the enormous locomotive engine, boiler, and steel works of the London and North Western Railway Company at Crewe, Messrs, MacCorquodale's Railway Printing Office, and several of the large collieries in the Wigan district were also inspected by the members on the remaining afternoon of this very successful meeting.

NOTES

THE Autumn Congress of the Sanitary Institute will be held at Croydon from the 21st to the 25th inst., under the presidency of Dr. B. W. Richardson. The exhibition will be opened at 3 P.M., on the 21st, and in the evening Dr. Richardson will give his presidential address. On the 22nd Dr. Alfred Carpenter will give the address in the Section of Sanitary Science and Preventive Medicine; on the 23rd Capt. Douglas Galton, in the Section of Engineering and Sanitary Construction; and in the evening Prof. Corfield will give a lecture to the Congress; on the 24th Mr. G. J. Symons will give the address in the Section of Meteorology and Geology. Saturday, the 25th, will be devoted to discussion. The results of the examinations conducted by the Institute having shown the necessity for some systematic plan of technical instruction in sanitary science, the Council have decided to establish a School of Hygiene in London, to be opened during the month of November next. The course of instruction will include the following subjects:—Preventive Medicine. Practical Sanitary Science—(*a*) Medical and Chemical; (*b*) Engineering and Constructive. Jurisprudence and Sanitary Law. The following

gentlemen have been appointed the first lecturers:—Preventive Medicine—Dr. B. W. Richardson, F.R.S.; Practical Sanitary Science: (a) Medical and Chemical—Prof. Corfield; (b) Engineering and Construction—Capt. Douglas Galton, R.E., C.B., F.R.S. Jurisprudence and Sanitary Law—Mr. W. H. Michael, Q.C., F.C.S. It is proposed that each session should occupy about twelve lectures, and the course will embrace the subjects included in the examinations of the Sanitary Institute of Great Britain and other examining bodies. The school will be open to all classes and to persons of either sex.

THE Social Science Congress was opened at Manchester yesterday, under the presidency of the Bishop of Manchester.

WE record with sincere regret the death of Mr. Henry Negretti, the well-known optician, and inventor of the deep-sea thermometer to which his name is attached. Mr. Negretti died on Wednesday last week at the age of sixty-two years. What his inventive genius did for the work of scientific research many of our readers know. His death is a real loss to science, as it will be to many who had substantial cause to know the depth of his generosity.

MR. R. J. USSHER, the explorer of the Pleistocene caves near Cappagh, Co. Waterford, has added to his discoveries a "sub-marine crannog." This is a new feature in reference to the Irish lake dwellings; for although some of them were known to be of very ancient date yet no trace of them had been recorded from the submerged bogs.

THE commemoration of the eighteenth centenary of the destruction of Pompeii—rather a strange event on which to hinge a celebration of any kind—appears to have been a great success. It attracted a large concourse of visitors, for whose delectation several excavations were made, and innumerable objects of great interest brought to light. One house excavated seems to have been a bird-seller's shop, judging from the small bones found, the little drinking vessels, and the quantities of millet and hemp seed, and what looked like small beans. The memorable feature of the commemoration, however, is the volume issued by the Directorate of the Museums of Naples. The eminent astronomer, Prof. Palmieri, contributes a paper on Vesuvius in the times of Strabo and Spartacus, and on the changes it underwent A.D. 79. The Chevalier Ruggiero discourses effectively on the eruption itself, and Signor Scacchi describes the houses demolished by lightning. The other fifteen contributions which complete the volume treat of every aspect of the public and private life of Pompeii.

THE second part of the magnificent "Herefordshire Pomona," brought out by the Woolhope Club, has been issued. We are pleased to hear that the work has been so successful that the club have resolved to increase the size of the parts, so as to complete the work as soon as possible. To the present part Dr. Bull contributes a curious and interesting paper on "Modern Apple Lore," as also "A Sketch of the Life of Lord Scudamore," with a very fine large portrait; and Sir H. E. C. Scudamore Stanhope a paper "On the Cordon System of Growing Pears." The part contains many plates of exquisitely coloured illustrations of varieties of apples and pears.

THE Engineering Laboratory, in connection with the Technical Department of University College, was opened to students yesterday. A private view to representatives of the press was given on Tuesday afternoon. The faculties of Arts and Laws and of Science were opened yesterday by an Introductory address by Prof. Charles Graham on Technical Education.

IN a paper on Experimental Determination of the Velocity of Light, read at the Saratoga meeting of the American Association by Mr. A. A. Michelsen, of the U.S. Navy, the author concludes as the result of an elaborate series of experiments, that the velocity of light *in vacuo* is 299,828 kilometres per second. See NATURE, vol. xviii. p. 195.

GENERAL MYER, the chief officer of the U.S. Signal Office, has issued the first number of a French edition of the meteorological observations taken at the several meteorological stations placed under his supervision.

M. ANGOT, Professor of Physics to the Lycée Fontanes, has been appointed meteorologist to the Central Bureau of Paris.

THE French Northern Railway Company posts up daily at its principal stations the warnings and weather maps, issued by the Central Bureau of Paris. The meteorological news of the principal sea-ports on the railway system of the Company are also noted.

A METEOROLOGICAL station, as we announced in our last impression, will be established at Mont de Mignons, in the vicinity of Nice. It should be added that an agronomical station will be placed in the same locality. The total expense is estimated at 40,000*l*.

THE special Museum of Algerian industrial and natural products, established in the Palais de l'Industrie twenty years ago, has been broken up. A part of it has been sent to the Museum of the French Colonies at the Ministry of Marine and Colonies, and the other to the Ethnographical Museum, which is being fitted up at the Trocadero.

IN a small pamphlet entitled "Notes from the History of my Parrot in Reference to the Nature of Language" (a reprint from the *Journal of Mental Science*) Dr. Samuel Wilks aims at proving that language, in its larger sense, has its rudimentary framework in the inferior creatures. The result of his observations as to the parrot's faculty of acquiring language are "that it has a vocal apparatus of a most perfect kind, that it can gather through its ear the most delicate intonations of the human voice, that it can imitate these perfectly by continued labour, and finally, hold them in its memory; also that it associates these words with certain persons who have uttered them; also that it can invent sounds corresponding to those which have emanated from certain objects."

THE terrific hurricane which passed over Brisbane and the suburbs on the night of June 23, unfortunately did some very serious damage in the Botanic Gardens and in the Acclimatisation Society's grounds. Numbers of large trees were torn up by the roots, and branches were scattered in all directions. At Bower Park numerous valuable trees and plants were injured, and it will take much time and labour to repair all the mischief.

THE *City Press* states that it is intended shortly to present the honorary freedom of the Leathersellers' Company to Prof. Owen.

BY the last mail from China we learn that there has been a severe earthquake in Western China, which is said to have caused serious damage in the provinces of Szechuen, Shensi, and Kansu. From Manila the intelligence also comes that Surigao has experienced several disastrous earthquakes which commenced on July 1. The shocks are described as even stronger than that felt there in 1875. Between July 1 and 13, beyond which latter date we have no news, no less than seventy shocks had been felt. The damage to houses had been considerable, but no lives had been lost.

MR. E. KNIPPING, of Yedo, has just published a *brochure* on the typhoons which occurred about a year ago in the China and Japan seas. Mr. Knipping has embodied in it the results of his own personal experience and information, derived from the loss of ships which were caught in the gales.

THE *Transactions* of the Norfolk and Norwich Society for 1878–9 contain, as usual, several papers of value. Mr. J. H. Gurney describes a visit he paid to "the Gannet City," as he calls the Bass Rock in the Firth of Forth. "Norfolk Decoys" is an interesting paper by Mr. T. Southwell, and Mr. John Cordeaux contributes "Some Recent Notes on the Avi-Fauna

of Lincolnshire," and Mr. H. B. Woodward a memoir of Samuel Woodward. Ornithological and Meteorological Notes for 1878, and Part 9 of the Fauna and Flora of Norfolk (Hymenoptera—Chrysididæ and Aculeata) by Mr. J. P. Bridgman fill up the volume.

WE learn from the annual report of the Central Meteorological Observatory at St. Petersburg, just appeared in the *Repertorium für Meteorologie* for the years 1877 and 1878, that the Observatory received accurate meteorological observations from 133 Russian stations.

"ACCIDENTS in the Comstock Mines and their Relation to Deep Mining" forms the subject of a recent paper to the American Institute of Mining Engineers, by Mr. Church, M.E. He points out that heat, the peculiar mode of timbering in square sets, the almost exclusive use of nitro-glycerine powders, the necesssity of frequent repairs to shaft timbers, the incessant movement of the rocks through which the shafts are sunk, making accidents in hoisting more than ordinarily frequent, and the necessity of transporting large quantities of rock through narrow gangways entirely by human labour, are the conditions in which mining in the Comstock may be said to suffer rather more than the usual liability to danger. Two of the causes, both connected with the movement of the ground, may be expected to increase with depth. Together with the heat they comprise 40 per cent. of the whole number of accidents. It is concluded that the conditions of deep mining will increase 40 per cent. of the causes which lead to casualties, leaving 60 per cent. unaffected.

THE silicates which form crystalline rocks (the formation of which is supposed to have occurred at a high temperature) allow of being fused in the laboratory, and the products of this fusion are of great geological interest. Not a few are chemically altered in the process, because they contain hydrogen or fluorine, or both. In a recent paper to the Berlin Academy Prof. Rammelsberg has discussed the behaviour of the two fluorine-containing silicates, topaz and mica, at a high temperature. It appears that out of both the fluorine is wholly or partly volatilised, escaping partly in the free state, partly in the form of fluorides. The two minerals, however, behave differently in that, whereas in the glowing mica the proportion of the electro-positive elements is not altered, in the glowing topaz a large quantity of silicium and a smaller of aluminium is wanting.

THE number of journals and reviews published in the twenty-two cantons of Switzerland is 519, of which 249 are political journals, 30 literary, 39 religious, &c. It is in the canton of Berne that most journals are published, viz., 71; then comes the canton of Zurich with 68; the cantons of Glarus and Uri have only 3 journals each.

A FRENCH populariser of science, Prof. Laurendeau, of Bordeaux, endeavours to give an idea of universal gravitation by using a terrestrial globe to which small figures are attached by means of pieces of caoutchouc. On pulling a figure from the globe, then letting go, it falls back wherever its position on the globe. Two such figures being attached on opposite sides of the globe, demonstrate that what we call high or low is merely greater or less distance from the centre of the globe. To illustrate the case of Saturn with its ring, Prof. Laurendeau uses a sphere rotated about a horizontal axis; in the equator of this sphere are arranged metallic sectors attached to the centre by threads of caoutchouc. On rotation commencing, the sectors come out, and by virtue of persistence of impressions on the retina, one sees Saturn's ring. Again, two balls of the same mass and volume are attached to suspended threads; the threads are twisted round each other, then left to untwist, whereupon the balls separate by centrifugal force, gravitating round a common centre between them. Then these balls are replaced by a large ball and a small one; and this time the small gravitates round the large. Once more a solid lead ball and a large inflated balloon, being similarly treated, the larger gravitates round the smaller, &c.

DR. J. PELLETAN in an article on Microscopes in *La Nature*, states that English microscopes are much superior to those made in France; the former comply with all the desiderata, while the latter are far behind. But the English are at least twice the price of the French. Nearly all cheap English microscopes, Dr. Pelletan states, are bad.

WE have received the programme of the course of lectures during the coming winter in connection with the Bristol Museum and Library, in which scientific subjects bear a prominent part. During the Christmas holidays Prof. S. P. Thompson will give three lectures on Frost, Ice, and Snow, and Mr. W. J. Sollas on Glaciers, Ice Action in the Arctic Regions, and Ice Action in the Past.

"EDISON'S FAST SYSTEM OF TELEGRAPHY" is the subject of a descriptive paper in the October *Scribner* and the occasion of the publication of a new portrait of the inventor by Francis Lathrop. This system is the little known Automatic Telegraph which for a year was in operation between New York and Washington, and attained the marvellous speed of several thousand words per minute, but has now disappeared in the litigation of rival companies. *Scribner* has now had papers on the three discoveries of Mr. Edison, which are regarded by him as the most important, viz.: the Electro Motograph principle (involved in Phonograph, Telephone, &c.), the Carbon Button and the Automatic Telegraph.

IN the Paris International Exhibition of Sciences applied to Industry luminous dials for clocks are now sold, on which the hour can be read during the whole of the night without the help of any light whatever. Although fading gradually the phosphorescence is sufficient to serve till daylight. Barometers and thermometers are said to be prepared on this principle for night balloon ascents when no moon is visible. These substances are prepared according to the principle defined by M. Edmond Becquerel in his work on Phosphorescence.

M. H. LESOUDIER, of Paris, will shortly publish a large work on the natural history of birds, entitled "Les Oiseaux dans la Nature; Description pittoresque des Oiseaux utiles." The authors are MM. Rambert and Robert. The work will contain no less than sixty chromo-lithographs, and will besides be profusely illustrated with woodcuts.

THE Nagasaki *Rising Sun* states that the prospects of another new coal mine on an extensive scale being shortly opened in the Island of Nakanoshima are looked upon as very promising. Preliminary operations were commenced some time ago, and it is understood that they are now nearly completed. The Island of Nakanoshima is situated about twelve miles from Nagasaki, and contains some fine seams of coal.

IN his just published report on the trade and commerce of Taganrog, Her Majesty's Consul tells us that a scourge in the shape of a destructive insect—the *Amsoplia austriaca* beetle—has revisited that region. It appeared in the steppe, sixty miles to the north of Taganrog, as well as at Mariapol, in immense swarms, and committed great devastation among the corn crops. These insects attack the new corn, and have destroyed many million roubles' worth of produce. They deposit their eggs at a depth of from three to four inches in the ground, preferring rich dark soil where wheat is grown to any other, and it is stated that the lapse of one, or even two years is necessary to complete the metamorphosis. It is asserted that, after the larva has quickened, the offspring buries itself deeper in the ground until it arrives at maturity.

The following works of scientific interest will be published by Messrs. Macmillan and Co., during the coming season:—"A Treatise on Comparative Embryology," by Mr. F. M. Balfour, F.R.S.; the second part of the second volume of Professors Roscoe and Schorlemmer's "Treatise on Chemistry"; this, which is just ready, completes the "Inorganic Chemistry;" Prof. Boyd Dawkins' "Early Man in Britain"; Prof. Gamgee's "Text-Book of the Physiological Chemistry of the Animal Body;" "Pharmacology and Therapeutics" and "Natural History in the Bible," by Dr. Lauder Brunton, F.R.S.; "A Manual of Geology," by Prof. Geikie, F.R.S.; "Structural Botany on the Basis of Morphology," by Prof. Asa Gray; "Blowpipe Analysis," from the German of J. Landauer, by Messrs. James Taylor and W. E. Kay; "Questions on Chemistry," by Mr. Francis Jones; "Easy Lessons on Heat," by Miss C. A. Martineau; "Easy Lessons on Light," by Mrs. F. E. Awdry; "A Handbook of Double Stars," with a Catalogue of 1,200 Double Stars and Extensive Lists of Measures for the Use of Amateurs, by Edward Crossley, F.R.A.S., Joseph Gledhill, F.R.A.S., and James M. Wilson, F.R.A.S., with Illustrations; and a new and thoroughly revised edition of "Pharmacographia," by Messrs. Flückiger and Hanbury. Prof. Huxley's "Introductory" to the Science Primers, has already been announced.

THE additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii*) rom South Africa, presented by Mr. E. Meyerstein; a Black Rat (*Mus rattus*) from Rangoon, presented by Mr. R. M. Middleton; a Norwegian Lemming (*Myodes lemmus*) from Norway, presented by Mr. James Shuter, F.R.C.S.; a Bonelli's Eagle (*Nisaetus fasciatus*) from Mogador, presented by Capt. W. P. Forwood; a King Parrakeet (*Aprosmictus scapulatus*) from New South Wales, presented by General Blake; a White-backed Piping Crow (*Gymnorhina leuconota*) from South Australia, presented by Mrs. Buchanan; a Silky Marmoset (*Midas rosalia*) from Brazil, a Malbrouck Monkey (*Cercopithecus cynosurus*) from West Africa, deposited; a Red-billed Tree Duck (*Dendrocygna autumnalis*) from South America, purchased; a Brown Bear (*Ursus arctos*) from Russia, received in exchange.

MOUNT ETNA

SHORTLY after the eruption of Mount Etna in May and June last M. H. de Saussure visited the mountain, and made a minute exploration of the region about the sources of the eruption. The results of this examination he describes in a series of letters in the *Journal de Genève* from June 17 to July 4, copies of which M. de Saussure has sent us, along with a note containing additional observations. On his first ascent he and his guide had to spend the night on Monte Temperossa in rather critical circumstances and with the scantiest supply of food and drink. Indeed, it seems to have taken a day or two after reaching a supply of water below ere M. de Saussure's thirst could be quenched. He had observed large patches of a deep black attached to the rocks, and had been puzzled to know what they were. His thirst, however, quickened his perception, and on scratching away about a centimetre of ashes he found underneath what he had half expected, beautiful white snow. The failure of this first excursion determined M. de Saussure to choose another point of departure than Lingugrossa, and to devote three days if necessary to traverse the neighbourhood of the cone. He thus succeeded in reaching the upper limits of the eruption on the north side. The crevasse which has been opened on Etna has divided the volcano into two parts. On the north face it extends to the valley which bounds the mountain; on the south face it seems to be arrested half way. Some of the details of the eruption have already been given in NATURE, vol. xx. p. 198. On the north face the large crevasse gave out two considerable streams, superposed in the same fault. The upper stream began in the neighbourhood of the cone of Etna, and was arrested to the east of Monte Pernicro. Thence the crevasse is quite exposed, and gave out only eruption of gas. Below Monte Pizzello there is formed a cone of ashes which gave out no lava. From this point the crevasses continue exposed to the ravine which separates Monte Nero from Monte Temperossa. Here are the sources and centres of the great lava stream which extend to near Mojo. M. de Saussure describes in detail the upper stream, which appears not to have been previously visited.

This eruption first appears at a height of about 2,700 metres, at the foot of the slopes of the upper plateau which supports the principal cone (Monte Morigibello). A violent explosion has here opened the side of the mountain, throwing out a mass of rocks, and forming a steep gulf in which the northern crevasse seems to terminate. Below this point of explosion the lava was thrown out in great abundance, and formed a current at first narrow, which afterwards inundated the slopes of a high plateau spreading over a distance of several kilometres. At the point of departure was formed a sugar-loaf cone of small height, which, on June 13, was still very active, and whence escaped with a hissing sound a thick smoke of vapours, mixed occasionally with great flames resulting from the combustion of gas. The lava was spread over a vast inclined plateau, flowing over very rough streams of recent lava, on which it is broken up to an infinite extent as far as the foot of a mountain with three craters (Monte Pernicio) which turns it to the east.

An important fact observed by M. de Saussure is that these lavas flowed over the snow, and that at the time of his visit even they rested on a thick bed of that substance. In fact, in all the faults of the lava, in all the openings, at the bottom of all the ravines resulting from the sinking of the lavas, snow was found, often several metres in thickness. Nothing proves better, M. de Saussure thinks, how bad a conductor of heat the eruptive matter is. The terminal end, as it rolls down, carpets the ground with blocks resulting from the continual rupture of the already solidified envelope, and thus forms a base on which afterwards flows the viscous current. At the same time a large mass of snow must have been melted. M. de Saussure saw traces of a large number of streams loaded with ashes which had been precipitated from all the rocks and washed the slopes of the snows, which extend much lower than the lava stream. One result of this eruption over snow is that the lava is mixed with a mass of mud, the melting snow diluting the dust resulting from the porphyrisation of the blocks at the same time as the shower of ashes from the great crater falls on the surface of the current. The fire and water ceaselessly intermingling by the mechanical action of the burning gravel, produced a sort of muddy marmalade, which, rapidly fusing by the persistent heat of the lavas, gave rise to clouds of vapour and left all the stream, all its blocks, all its pebbles, covered with a layer of dry mud, which turns into dust and gives to the new lavas a grey colour which prevents them from being distinguished at a distance from old lavas.

Below the upper lavas the slopes which extend in the direction of Monte Nero are covered with vast fields of hard and deep snow. Their surface is all strewn with yellow spots, so that at a distance they seem covered with sulphur. This appearance is due to the abundant efflorescence of ferrous chloride which condenses on the surface of the snow, and which has formed small mound-like masses, mixed to a small extent with agglutinated ashes. The whole of the snow is, moreover, covered with patches of hardened mud of the size of a plate, and even much larger, also ornamented with yellow efflorescence, and mostly cracked like dried mud or split from bottom to top by a push which has raised them and broken them into a star-like shape. M. de Saussure thinks that these singular accidents are due to deep emanations, and seem to show that under the snow the ground is riddled with crevasses in direct communication with the volcanic centre. The acid vapours reaching the lower surface of the snow are there condensed by the cold; but gradually they reach the surface, and have then formed an infinite number of small sources, which are charged with mud because the ashes of the old subjacent lavas have been diluted with water resulting from the condensation of vaponr against the under surface of the snow, increased by the snow melted by the heat of these same vapours. After quitting the snows, an immense area of sand-hills is met with covered with blocks from the crater of Etna.

M. de Saussure paid a visit to the great cone of Etna in company with an English and an American tourist. As they were walking over the lower slopes of the cone of ashes, he observed a small crack in the fine sand which covered the ground. This soon ceased to be visible, and suddenly M. de Saussure saw a much larger crevasse open under his feet, and he felt at the same time the ground begin to glide down the steep slope. He fled

as fast as he could, and reached a solid standing-ground, but not before perceiving that the guide, who walked behind him, had sunk up to the middle in the sand, and indeed soon disappeared. All the slope sank with increasing swiftness, swelling out at the bottom and opening out to give forth a stream of mud of at least ten metres in height, which shot like a wild torrent across the plateau, and precipitated itself towards the Val de Bove. Immediately all the moving sand, to more than thirty metres in height, was diluted and drawn along, as were also the stones and blocks it contained, and which rolled over each other pell-mell. Fortunately they succeeded in extricating the guide, covered with mud, torn and bruised.

Seeking the origin of these eruptions of mud, M. de Saussure observes first that they take place in the neighbourhood of the central cone of Etna, and that they all escape from the foot of the cone and the very inclined slopes which support it. They proceed then exclusively from the water stored in the beds of ashes. These causes seem to account for this mass of water. 1. The hot vapours. The cone seems almost exclusively composed of ashes and movable stones, and during the eruption an enormous mass of vapour must have traversed it. There are, moreover, numerous fumeroles in the upper part. These vapours have been condensed, all the more readily that they have encrusted the mantle of snow which envelops the summit of the mountain. 2. The melting of this snow, determined less by the fall of ashes on the surface than by the heat which radiates from the interior and the vapours which traverse the porous mass of the cone. 3. The abundant vapours falling from the cloud of vapours projected by the crater. The two first causes are the most important; the last has most especially given rise to surface streams, the traces of which are apparent. The water gradually collecting in excess in the lower parts of the cone, ends by forming these enormous deposits, which, at a given moment, yielding to their weight, cause an eruption to the outside, turning over and diluting the beds of ashes which oppose its exit.

In a communication to us M. de Saussure gives an analysis of the little mud-heaps which have projected through the snow. They are composed of a grey powder formed of pozzolana (spongy amorphous silicates), white, grey, and black (augite), mixed with (*b*) amorphous sulphur (yellow and orange coloured); (*c*) calcium sulphate (hydrated) in numerous well-defined small crystals; (*d*) sodium and potassium sulphate; (*e*) calcium and potassium chloride; (*f*) perchloride of iron and oxychloride of iron; (*g*) indication of copper salts.

The crystals are all of alabaster, and so wet that they can only have been formed after the eruption of the mud in drying. There is no crystallised silica nor feldspar. The sulphur in the mud is curious to observe. It must have condensed out of the eruptive vapours which formed the water to make the mud by mixing with old ashes under the snow, and by their expansion driven small quantities of that mud through the snow. This mud, when heated, evaporates sulphur, sulphurous and sulphuric acid, some perchloride of iron, and some hydrochloric acid.

THE ACTION OF HEAT IN VACUO ON METALS[1]

IN the course of my experiments on electric lighting I have developed some striking phenomena arising from the heating of metals by flames and by the electric current, especially wires of platinum, and platinum alloyed with iridium. These experiments are in progress.

The first fact observed was that platinum lost weight when heated in a flame of hydrogen, that the metal coloured the flame green, and that these two results continued until the whole of the platinum in contact with the flame had disappeared. A platinum wire four-thousandths of an inch in diameter, and weighing 306 mgrms., was bunched together and suspended in a hydrogen flame. It lost weight at the rate of a fraction less than 1 mgrm. per hour as long as it was suspended in the flame. When a platinum wire is stretched between two clamping posts, and arranged to pass through a hydrogen flame, it is coloured a light green; but when the temperature of the wire is raised above that of the flame, by passing a current through it, the flame is coloured a deep green. To ascertain the diminution in the weight of a platinum wire when heated by the electric current, I placed between two clamping posts a wire five-thousandths of an inch in diameter, and weighing 266 mgrms. This wire, after it was brought to incandescence for twenty minutes by the current, lost 1 mgrm. The same wire was then raised to incandescence; for twenty minutes it gave a loss of 3 mgrms. Afterwards it was kept incandescent for one hour and ten minutes, at which time it weighed 258 mgrms.—a total loss of 8 mgrms. Another wire, weighing 343 mgrms., was kept moderately incandescent for nine consecutive hours, after which it weighed 301 mgrms., showing a total loss of 42 mgrms. A platinum wire twenty-thousandths of an inch in diameter was wound in the form of a spiral one-eighth of an inch in diameter and one-half an inch in length. The two ends of the spiral were secured to clamping posts, and the whole apparatus was covered with a glass shade 2½ inches in diameter and 3 inches high. Upon bringing the spiral to incandescence for twenty minutes that part of the globe in line with the sides of the spiral became slightly darkened; in five hours the deposit became so thick that the incandescent spiral could not be seen through the deposit. This film, which was most perfect, consisted of platinum, and I have no doubt but that large plates of glass might be coated economically by placing them on each side of a large sheet of platinum, kept incandescent by the electric current. This loss in weight, together with the deposit upon the glass, presented a very serious obstacle to the use of metallic wires for giving light by incandescence, but this was easily surmounted after the cause was ascertained. I coated the wire forming the spiral with the oxide of magnesium, by dusting upon it finely powdered acetate of magnesium: while incandescent the salt was decomposed by the heat, and there remained a strongly adherent coating of the oxide. This spiral so coated was covered with a glass shade, and brought to incandescence for several minutes; but instead of a deposit of platinum upon the glass, there was a deposit of the oxide of magnesia. From this and other experiments I became convinced that this effect was due to the washing action of the air upon the spiral; that the loss of weight in and the coloration of the hydrogen flame were also due to the wearing away of the surface of the platina to the attrition produced by the impact of the stream of gases upon the highly incandescent surface, and not to volatilisation, as commonly understood; and I venture to say, although I have not tried the experiment, that metallic sodium cannot be volatilised in high vacua by the heat derived from incandescent platinum; any effect that may be produced will be due to the washing action of the residual air. After the experiment last described I placed a spiral of platinum in the receiver of a common air-pump, and arranged it in such a manner that the current could pass through it, while the receiver was exhausted. At a pressure of 2 millimetres the spiral was kept at incandescence for two hours before the deposit was sufficient to become visible. In another experiment, at a higher exhaustion, it required five hours before a deposit became visible. In a sealed glass bulb, exhausted by a Sprengel pump to a point where a quarter of an inch spark from an induction-coil would not pass between points 1 millimetre apart, was placed a spiral, the connecting wires passing through the glass. This spiral has been kept at the most dazzling incandescence for hours without the slightest deposit becoming visible.

I will now describe other and far more important phenomena observed in my experiments. If a short length of platinum wire one-thousandth of an inch in diameter be held in the flame of a Bunsen burner, at some part it will fuse, and a piece of the wire will be bent at an angle by the action of the globule of melted platinum; in some cases there are several globules formed simultaneously, and the wire assumes a zigzag shape. With a wire four-thousandths of an inch in diameter this effect does not take place, as the temperature cannot be raised to equal that of the smaller wire, owing to the increased radiating surface and mass. After heating if the wire be examined under a microscope, that part of the surface which has been incandescent will be found covered with innumerable cracks. If the wire be placed between clamping posts, and heated to incandescence for twenty minutes, by the passage of an electric current, the cracks will be so enlarged as to be seen with the naked eye; the wire, under the microscope, presents a shrunken appearance, and is full of deep cracks. If the current is continued for several hours these effects will so increase that the wire will fall to pieces. This disintegration has been noticed in platina long subjected to the action of a flame by Prof. John W. Draper. The failure of the process of lighting invented by the French chemist Tessie du Motay, who raised sheets of platinum to incandescence by

[1] A Paper read by Mr. T. A. Edison before the American Association for the Advancement of Science; Saratoga Meeting.

introducing them into a hydrogen flame, was due to the rapid disintegration of the metal. I have ascertained the cause of this phenomenon, and have succeeded in eliminating that which produces it, and in doing so have produced a metal in a state hitherto unknown, and which is absolutely stable at a temperature where nearly all substances melt or are consumed; a metal which, although originally soft and pliable, becomes as homogeneous as glass and as rigid as steel. When wound in the form of a spiral it is as springy and elastic when at the most dazzling incandescence as when cold, and cannot be annealed by any process now commonly known, for the cause of this shrinking and cracking of the wire is due entirely to the expansion of the air in the mechanical and physical pores of the platinum, and the contraction upon the escape of the air. Platinum as sold in commerce may be compared to sandstone, in which the whole is made of a great number of particles with many air spaces. The sandstone upon melting becomes homogeneous and no air spaces exist.

With platinum or any metal the air spaces may be eliminated and the metal made homogeneous by a very simple process. This process I will now describe. I had made a large number of platinum spirals, all of the same size and from the same quality of wire; each spiral presented to the air a radiating surface of three-sixteenths of an inch; five of these were brought by the electric current up to the melting-point, the light was measured by a photometer, and the average light was equal to four standard candles for each spiral just at the melting-point. One of the same kind of spirals was placed in the receiver of an air-pump, and the air exhausted to 2 millimetres; a weak current was then passed through the wire, to slightly warm it for the purpose of assisting the passage of the air from the pores of the metal into the vacuum. The temperature of the wire was gradually augmented, at intervals of ten minutes, until it became red. The object of slowly increasing the temperature was to allow the air to pass out gradually and not explosively. Afterward the current was increased at intervals of fifteen minutes. Before each increase in the current the wire was allowed to cool, and the contraction and expansion at these high temperatures caused the wire to weld together at the points previously containing air. In one hour and forty minutes this spiral had reached such a temperature without melting that it was giving a light of twenty-five standard candles, whereas it would undoubtedly have melted before it gave a light of five candles had it not been put through the above process. Several more spirals were afterwards tried, with the same result. One spiral, which had been brought to these high temperatures more slowly, gave a light equal to thirty standard candles. In the open air this spiral gave nearly the same light, although it required more current to keep it at the same temperature. Upon examination of these spirals, which had passed through the vacuum process, by the aid of a microscope no cracks were visible; the wire had become as white as silver, and had a polish which could not be given it by any other means. The wire had a less diameter than before treatment, and it was exceedingly difficult to melt in the oxy-hydrogen flame. As compared with untreated platinum, it was found that it was as hard as the steel wire used in pianos, and that it could not be annealed at any temperature.

My experiments with many metals treated by this process have proved to my satisfaction, and I have no hesitation in stating that what is known as annealing of metals to make them soft and pliable is nothing more than the cracking of the metal. In every case where a hard drawn wire had been annealed a powerful microscope revealed myriads of cracks in the metal. Since the experiments of which I have just spoken I have, by the aid of Sprengel mercury pumps, produced higher exhaustion, and have, by consuming five hours in excluding the air from the wire and intermitting the current a great number of times, succeeded in obtaining a light of eight standard candles from a spiral of wire with a total radiating surface of 1-32nd of an inch, or a surface about equal to one grain of buckwheat. With spirals of this small size which have not passed through the process, the average amount of light given out before melting is less than one standard candle. Thus I am enabled, by the increased capacity of platinum, to withstand high temperatures, to employ small radiating surfaces, and and thus reduce the energy required for candle light. I can now obtain eight separate jets, each giving out an absolutely steady light, and each equal to sixteen standard candles, or a total of 128 candles, by the expenditure of 30,000 foot-pounds of energy, or less than one horse-power. As a matter of curiosity I have made spirals of other metals, and excluded the air from them in the manner stated. Common iron wire may be made to give a light greater than platinum not heated. The iron becomes as hard as steel, and just as elastic. Nickel is far more refractory than iron. Steel wire used in pianos becomes decarbonised, but remains hard, and becomes the colour of silver. Aluminium melts only at a white-heat.

In conclusion, it may be interesting to state that the melting-points of many oxides is dependent on the manner of applying the heat; for instance, pure oxide of zirconium does not fuse in the flame of the oxy-hydrogen blow-pipe, while it melts like wax and conducts electricity when on an incandescent platinum spiral which is at a far lower temperature; on the other hand oxide of aluminum easily melts in the oxy-hydrogen flame, while it only vitrifies on the platinum spiral.

THE INAUGURATION OF ARAGO'S STATUE

THE statue to Arago recently unveiled at Perpignan is not the first erected to that great astronomer and greater physicist. In 1867 M. Isaac Pereire, then representative of the native place of Arago in the Imperial Chamber of Deputies, erected one at his own expense at Estagel. The inauguration was accompanied by speeches delivered by the generous donor, M. Bertrand, the perpetual secretary of the Academy of Science, and others. It was stated then that Arago had supported against his own party the construction of the railways by public companies, and had been grossly abused by some of his political friends. Although a political leader, it must be said, to the glory of Arago, that he never was influenced by party considerations. He was always writing, and speaking, and voting according to the *dictamina* of his own judgment. These facts should be remembered, as efforts have been made in the recent Arago celebration, to degrade him into a mere politician, which never was the case. Arago was made a member of the Provisional Government of France in February, 1848; it was owing to his personal exertion that the abolition decree was proclaimed before the convocation of the National Assembly. It is true that he was appointed in the beginning of May one of the *quinquemvirs* of the Executive Commission. But this Government was overthrown by the popular rising of the end of June, and from that time he abstained from taking any prominent part in politics.

Arago was not rich, his works having been mostly published in the *Annuaire du Bureau des Longitudes* without any copyright, and sold for the benefit of the Bureau, of which he was the most influential member. His paying works were all of them posthumous, and edited by M. Barras, the Perpetual Secretary of the Agricultural Society of France. The sale was not so large as anticipated, and the publisher who purchased the copyright from the inheritors failed. The sale of the *Annuaire* was so large during Arago's lifetime, that the Bureau had a profit by it. Since his death it has become necessary to provide special funds for the publication of that useful work.

Arago had no salary at all as director of the Observatory. He was appointed every year by the Bureau, receiving only 200*l.* for his membership. His other salaries were 50*l.* as a member of the Academy of Sciences, 250*l.* as Perpetual Secretary, and when he was lecturing on astronomy 50*l.* The functions of deputy and member of Municipal Council of Paris being entirely gratuitous, he was no receiver of any other public moneys. Under the Republic his membership of the Assembly brought him 1*l.* a day.

From the eloquent *éloge* pronounced by M. Paul Bert at the recent inauguration, we take the following extract:—

"To contemplate Arago under all the aspects that may attract the admiration of posterity we must think of him as a man of science overturning the Newtonian hypothesis of the emission of light, determining the physical constitution of the sun, explaining the scintillation of the stars, the nature of the aurora borealis, discovering magnetisation by currents, the origin of the electric telegraph, extending to all bodies magnetic properties; finally, for I must limit myself to the most prominent points, indicating to the most eminent of his disciples the star still unknown and invisible, whose discovery introduced order among the perturbed planets, and which still remains the most extraordinary mark of the power of human genius. As a professor, again, before three thousand auditors at the Observatory, or in his chair as Perpetual Secretary writing his incomparable scientific notices, or dictating, when blind, his popular astronomy, always, by speech or by pen, marvellous for his clearness, his

accuracy, his power and fulness, elevating all he touched, returning to the astonished inventor his discovery developed and fertilised, sowing broadcast his ideas, and rejoicing when others, friends or foes, were enriched by the precious fruits of his genius. As a scientific historian he excelled Condercet, equalled Cuvier and Fontenelle, and was characterised above all others by his eagerness to give every one his due, and his jealous love of justice. As an orator he carried into the tribune the vigour and clearness of the scientific chair, vivified by the emotions of master-spirits, and dominating the assembly by his lofty stature, with his beautiful Southern head, and his eye full of fire. He was a man, in fact, in whom the will to act was united with the consciousness of power, an intelligence marvellously comprehensive and powerfully creative, so bold and yet so prudent at times that it never commited an error that required to be retracted. Of an ardent but loyal nature, ready for power, but incapable of hatred, and thirsting for justice, a heart sensitive and valiant, sometimes drawn, says a contemporary, to show itself severe to the strong in order to support the weak; a soul austere but a brow serene; a father and citizen worthy of the ancient legends, and able, like Carnot on quitting life to bear the noble witness: —'My hands are clean and my heart pure.' From the extent of the sketch you may judge what will be the nature of the picture."

PALÆOZOIC ROCKS IN SOUTH-EAST OF ENGLAND[1]

IN a communication to the Geological Section of the meeting of the British Association at Plymouth in 1878, I called attention to the significance of the result of the deep boring at Messrs. Meux's; as to the upper Devonian beds there met with next beneath the cretaceous strata; also as to the importance of some further knowledge as to the direction of the dip of the said upper Devonian beds. An accurate acquaintance with this point is essentially needed with reference to its immediate bearing on a question which may possibly become one of national importance, namely, the place of the true coal measure series beneath our south-eastern area, and which must serve as an excuse for another short communication on the same subject.

The question involved has attracted the attention of sundry foreign geologists during the past year, and upon our own area facts have been ascertained which now enable us to arrive inferentially at what, but a year since, was mere speculation.

M. Dewalque, at a recent meeting of the Belgian Geological Society, remarked first on the absence of Jurassic and Triassic deposits, as along the palæozoic ridge extending from the Ardennes by the north of France, being just what the borings at St. Trond, Laecken, Menin, and Ostende would indicate. Secondly, that inasmuch as the palæozoic formations of Belgium and the north-west of France are extended into England, it is an important point, with reference to the prolongation of the Belgian coal-basin, that London should be known to be situated immediately over a formation, which is itself so close to the coal measures. "The supposition that the dip of these upper Devonian beds is to the south, and that they belong to the extension of our northern basin is that which is the most probable. The coal formation may therefore occur at a short distance south of London, and at a workable depth.

"With a southern dip it may be that these beds (upper Devonian) belong to the extension of our southern basin. In this case coal may occur in the north as well as in the south, and nearer on this side (north) than on the south. Should there be such a coal basin, it might be as useless as ours (Belgium) of the Condros and the Entre Sambre and Meuse." The exact significance of this latter alternative of the Belgian geologist may not, perhaps, be understood by English geologists generally, as it has reference to a feature in the physical structure of Belgium, but the which is very properly referred to by M. Dewalque, now that the palæozoic band of the Continent is known to reach our south-east district. The band of Belgian and North of France coal-measures may be truly represented as trough-shaped, however produced.

M. Dewalque adds: "Starting from the supposition that our (Belgian) old strata are prolonged westward into England, and from the fact that upper Devonian strata occur under London, we are led to admit that the band of Silurian slates of the Ostende boring must pass north of London. These slates must be separated from the upper Devonian by other beds, such as the black slates of the Menin Shaft, which are Silurian. Considering the geographical position of these three places, together with the east and west direction of our older formations, it would not seem that their prolongation into England would carry them sufficiently north of London, so that the Devonian beds there should represent our Condros basin, and not that of Namur. If, then, at that place (London) we are in a prolongation of the Namur basin, the strata at Meux's must dip south; consequently it is most probable that the coal-measures are to be found at a short distance south."

Such were the inferences drawn by M. Dewalque in 1878 from the results of the boring at Messrs. Meux's.

The supposition that the Silurian strata met with at Ostende would in their course westwards run north of London have been proved by the occurrence of beds of Wenlock age at Ware, near Hertford, twenty miles north of London. This discovery has come most opportunely to supply the information which only a year since was needed, as to the dip of the upper Devonian strata at Messrs. Meux's brewery. The succession of the palæozoic strata in this the English side of the channel, even into the far west, is just what it is in Belgium and the north of France, from Brussels and Ostende from north to south. There the successive members of the series mostly rise to the surface and are exposed in all the valley of denudation extending north from the line of the coal measures, as long since laid down by Dumont.

With this guidance, and in spite of the little as yet known with respect to our own underground structure on the south-east, it can be safely put in relation with what obtains on the European continent for an extent of 400 miles; the order in which the successive members of the palæozoic series rise to the surface from beneath one another there, may be taken as our guide on to the order and relation of the upper Devonian at the end of Tottenham Court Road near Oxford Street, and the section at Ware.

The question of the strike and direction of the dip of the beds at Messrs. Meux's is now determined as forming part of the northern band of the trough containing first, the mountain limestone series, and, next above, the true coal measures.

For practical guidance one point alone remains to be considered: from the place of the Upper Devonian strata in the heart of London, what must be allowed for the breadth of the outcrop of mountain limestone series next in sequence? In parts of Belgium the mountain limestone has been estimated at 600 feet thick; it is less than that in an east and west direction. The nearest place to London at which this is exposed is in the north of the Boulonnais denudation; where, with its associated beds, it may be put at 400 feet. The breadth of such a mass at its outcrop, and with an angle of 30° to 35°, such as the Devonian bed at Meux's had, would be nearly doubled, or about 800 feet; in other words the lower members of the coal measure formation may be fairly expected to occur at about that distance south from a corner of Tottenham Court Road and Oxford Street. The upper, or productive coal-measures, still further to the south.

What has been ascertained beyond all doubt as to the line of section underlying a part of our English area from London to Ware, may safely be taken as holding good for a great extent of country on the east as in the west. The ages of more modern overlying formations do not affect this question, as is shown by the borings now in England, but more abundantly in the European continent. In our attempts to trace accurately hidden physical arrangements of the earth's crust, the restrictions to be observed are—the positive data of the ascertained thickness of the several formations and their several positions, and which enable us to replace, without much chance of error, the line of each band and of its angle of dip.

[1] "Further Evidence on the Range of the Palæozoic Rocks beneath the South-East of England," by R. A. C. Godwin-Austen, F.R.S. Paper read at the Sheffield meeting of the British Association.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

UNIVERSITY COLLEGE, BRISTOL, will shortly commence its fourth Session. The calendar, which is before us, states that there were 448 students in the college in the second session; and in the third, 576, of whom 355 were men and 221 women; 172 came in the day-time and 404 in the evening. Good progress is being made by the Engineering Department, which is designed to afford a thorough scientific education for students intending to become mechanical or civil engineers, surveyors, or architects. The course for engineering is such that students can pursue it during the six winter months of each year, and the council of the

college have arranged with the leading civil and manufacturing engineers in the neighbourhood to receive in their offices and workshops during the summer months, students whose position relatively to the firms would be that of articled pupils. Many of the recent developments in the scheme of instruction in the college are designed to meet the wants of the department. There are in addition general courses in Chemistry, Mathematics, Mechanics, Engineering, Experimental Physics, Surveying, Geometrical Drawing, Geology, Botany, Political Economy, Logic, Law, Modern History, English Literature, Greek, Latin, Ancient History and Literature, French and German. There are evening classes at low fees in most of these subjects. The college is also giving, with the co-operation of the Company of Clothworkers, instruction at Stroud in Chemistry and the Textile Industries. The subject of Logic has been added to the curriculum this year, and lectures on it will be given by Prof. Fanshawe, Fellow of New College, Oxford, who has recently been elected to the post of Classical Professor. The opening lecture of the session is to be given by him on Monday, October 6th, on "The Conditions of Intellectual Progress."

A PRIVATE society under the presidency of Dr. Kummer, Federal Director of the Statistical Board, and which already numbers 200 members, is about to open at Bern a permanent exhibition of educational objects. The exhibition comprises a collection of plans of schools, and of objects for teaching which may be considered as models for schools; a collection of publications (text-books, manuals, &c.), a collection of laws and regulations concerning schools, as well as of reports and school statistics published in Switzerland and elsewhere, and a collection representing the modes of teaching introduced in Swiss schools of all degrees, from Kindergarten to lyceums and universities. Numerous objects from the Swiss cantons and foreign countries have already arrived, and the exhibition will be opened for the public on October 15.

WE learn from the annual report of the University at Odessa, just appeared, that the university numbered 325 students and thirty-nine professors.

SCIENTIFIC SERIALS

THE *Verhandlungen der k. k. zoologisch-botanischen Gesellschaft in Wien* (1878, part ii., and 1879, part i.), contain the following papers:—On the shrub-lichens of Lower Austria; a catalogue of all the species observed in this province, by J. Eman Hibsch.—Mycological researches, by Steph. Schulzer von Müggenburg (3rd paper).—On the diptera-genera *Argyra macq.* and *Leucostola lev.*, by Ferdinand Kowarz.—Account of a coleopterological excursion through Carniola, Carinthia, and Styria, undertaken during the summer of 1878, by Ludwig Miller.—On *Thysa pythonissæ formis*, Kempelen, by Otto Hermann.—On *Amphipogon spectrum*, Whlb., and its position in systematic zoology, by Josef Mik.—On a method for drying freshly collected insects, by Brunner von Wattenwyl.—Review of the arachnida collected by Dr. Otto Finsch in Western Siberia, by Dr. L. Koch.—Bibliographica ornithologica, by Victor von Tschusi Schmidhoffen. This forms a complete catalogue of the whole ornithological literature of the Austro-Hungarian Empire.—On a copious appearance of centipedes, by Josef Paszlavszky.—Researches on æolidiadæ, by Dr. Rudolph Bergh (6th paper).—On the systematics of psyllodæ, by Dr. Franz Löw.—New researches on the fungus-flora of Vienna, by Felix von Thümen, and Wilhelm Voss.—Dipterological notes, by Josef Mik. These papers contain a treatise on *Trochobola cæsarea*, O. S., on *Cyrtopogon meyer dürii*, Mik., and on *Hypocharassus gladiator* the latter being a new species of dolichopodidæ from North America.—On the comparative flora of Wisconsin (2nd supplement), by Th. A. Bruhin.—Researches on the ant-fauna of Asia, by Dr. Gustav Mayr.—On the cultivation of bathing sponges, by Dr. Emil von Marenzeller.—On the history of evolution of the prothallium of *Scolopendrium*, by Dr. Günther Beck.—Researches on the literature and distribution of *Hepaticæ* in Bohemia, by Jos. Dedecek.—Coleopterological results of an excursion to Croatia and Slavonia, by Edmund Reitter, Dr. Eppelsheim, and Dr. von Heyden.—Synonymical observations referring to Bolivar's "Catalogus Orthopterorum Europæ," by Dr. Hermann Krauss.—Researches on two *Pemphigus* species, by Dr. Franz Löw.—Classification tables of European Coleoptera, (first paper containing *Cucujidæ*, *Telmatophilidæ*, *Tritomidæ*, *Mycetaeidæ*, *Endomychidæ*, *Lyctidæ*, and *Sphindidæ*.—On the first stages of two turnip flies, (1) the metamorphosis of *Lonchæa chorea* Meigen, (2) the turnip fly *Anthomyia conformis*, Nödlinger.—Zoological account of the expedition to Western Siberia in 1876, undertaken by order of the Bremen Society for North Polar Expeditions, by Dr. Otto Finsch, Dr. A. Brehm and Count Karl von Waldburg-Zeil-Trauchburg. This elaborate paper treats of the mammals, birds, amphibia and fishes of Western Siberia.—On some new American spiders, by Count Eugen Keyserling.—Lichenological excursions in the Tyrol (20th chapter, Prendazzo), by Dr. F. Arnold.—On some new Tyrolese *Sphegidæ*, by Franz Friedrich Kohl.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, September 22.—M. Daubrée in the chair.—The following papers were read:—On evolution in medicine, by M. Sedillot. The sagacious character of the Hippocratic ideas is demonstrated by the evolution of modern medicine.—Influence of atmospheric electricity on the growth, flowering, and fructification of plants, by M. Naudin. M. Grandeau, from experiments with tobacco and maize, affirmed florescence and fructification to be retarded and impoverished by withdrawal of plants from atmospheric electricity (by means of iron or wooden cages placed over them, the proximity of trees, or other bodies attracting atmospheric electricity). M. Naudin, from an extension of such experiments, thinks the influence of atmospheric electricity on plants is complex and far from being understood as yet. It is probably modified first by the nature of the plant species, then by climate, season, temperature, degree of light, dry or wet weather, perhaps, too, by the geological structure or mineralogical composition of the soil, whose layers do not equally conduct electricity. Possibly, too, tree species do not all withdraw the electric influence in the same degree.—Theoretical essay on the law of Dulong and Petit; case of perfect gases, by M. Willotte.—A work by MM. Franchet and Savatier, on the plants of Japan, was presented. It gives nearly 3,000 species, about one-fourth of which have not before been indicated in that country, and more than 200 of which are absolutely new. The work is made available for naturalists of the country by means of a table of Japanese synonyms.—On the organisation and classification of the Orthonectida, by M. Giard.—Meteorological observations at Montsouris Observatory in August (table).

EDUCATION

Education, its Principles and Practice, as Developed by George Combe, Author of "*The Constitution of Man.*" Collated and Edited by William Jolly, H.M. Inspector of Schools. (London: Macmillan and Co., 1879.)

THIS book appears at an opportune moment. Inquiries into the philosophy of education are attracting increased attention among teachers, and the universities are taking measures with a view to bring to light the best rules for school teaching, and the principles which underlie those rules. In these circumstances, the laborious editor of this volume has done a public service, in placing on permanent record and in a modern form, the principal writings of one of the most original thinkers and earnest workers in the department of educational reform. But for such an enterprise, the speculations of Combe, many of which originally appeared in a fugitive form, or in books which are now well-nigh forgotten, would have remained unknown to the present generation; although some at least of his teaching is as much needed now as half a century ago, when it first appeared.

George Combe was born in 1788, and the seventy years of his life coincided with the period in which the national conscience became awakened to the necessity for public instruction; and in which occurred the principal experiments and controversies that have slowly shaped our present national system. His attention was very early directed to the defects, both in the supply of means for education and in the character and quality of such education as was then accessible to the people. A large part of his life was devoted to the exposition and propagation of his views on these subjects. Those views may be thus briefly summarised:—(1) A true science of education should be based on a knowledge of physiology and of mental philosophy. (2) School teaching should be mainly directed to the training of faculties, with special reference to the actual pursuits and duties of life. (3) Hence the study of our own physical constitution, of the phenomena of nature, and of the economic and social laws which govern the happiness of communities, ought to supersede many of the subjects included in the ordinary school routine, much of which he regarded as mere verbiage and as very sterile of intellectual result. (4) While increased attention ought to be given in schools to ethics and religion, in so far as they are deducible from the laws of our own well-being and that of society, the public school ought not to concern itself with dogmatic theology in any form. (5) Special efforts ought to be made to train girls, both to a stronger interest in intellectual pursuits, and to a better understanding of the laws of health and the right way of training young children. (6) A true knowledge of the science of mind for the purposes of education is to be obtained only through phrenology; and the study of this subject is not only indispensable to the teacher and the parent, as the guide to right training; but should also be introduced into the curriculum of the school itself.

These cardinal doctrines were set forth by Combe in his larger works on Phrenology, and on the Constitution of Man; in numerous pamphlets and contributions to periodicals; as well as in lectures delivered in many places, both in England and America. His writings are characterised by clearness, and by considerable wealth and variety of illustration; and by the unadorned and forcible style which comes rather from strong conviction and definite purpose than from conscious literary effort.

To bring together from many books, tracts, and reports of lectures a coherent statement of Combe's teaching was a difficult task. And in one respect his present editor has succeeded. Mr. Jolly is in full sympathy with his author, and has diligently studied his writings. He has acquainted himself with the collateral history of the chief movements in which Combe took part, and has brought down the record both of his achievements and of their results to the latest period. As one of the most energetic and thoughtful of Her Majesty's Inspectors of Schools, and as a careful student both of the history and of the philosophy of the pedagogic art, Mr. Jolly possesses some exceptional qualifications for the task he has undertaken.

Yet, although the book is complete and exhaustive, and is logically arranged, it cannot be said to have been skilfully or artistically edited. Combe's life was spent in a sort of missionary work, in expounding and enforcing to very different audiences, and with varied illustrations, a few principles which he held to be of paramount importance. It was inevitable that he should repeat what was substantially the same thing many times. One might have expected that an editor would select from the voluminous material before him the most effective statement of each of Combe's doctrines, and present them in a concise form likely to attract a modern reader. But Mr. Jolly has preferred to bring together lengthy extracts, and to produce a huge amorphous volume of 800 pages, with manifold reiteration of the same facts and speculations in every variety of form. The book is filled with cross-references, and furnishes quite a curious study of the mode in which a limited number of ideas and facts admit of being stated and restated, combined and recombined, looked at from all sides, and made to occupy the maximum of space. All Mr. Jolly's reminiscences and illustrations seem to revolve round the three or four eminent men, who have more or less adopted Combe's views, and the little group of secular schools—of which it seems that very few now survive—in which those views were most fully carried out. And the repeated reference to the same names becomes after a time not a little wearisome even to the most patient and sympathetic reader.

The book will enable this generation to estimate with tolerable accuracy Combe's true place in the history of education. On the need of scientific instruction, and of training the observant and reasoning powers by the study of natural phenomena, his teaching was much in advance of his own age. His vindication of the importance of some acquaintance with the structure and functions of our own bodies, and with the constitution of man and of society; and especially his demand that the laws affecting wages and capital, and the conditions of industrial success should be taught to children are sound and far-seeing and even now await fuller public recognition. The scant acceptance these doctrines have received from the promoters of public education is largely owing to the use of the word "secular" in connection with Combe and his

favourite schools, and to the unfortunate associations which have happened to cluster round that word. But Combe was an earnestly religious man, and in his view both natural and revealed religion were vital parts of education. He wished, it is true, to exclude controversial theology from the common school; but he strongly advocated the teaching of the Christian faith by clergy and parents at other than school hours. And in the school itself he thought that moral training—the cultivation of benevolence, reverence, and truthfulness—was indispensable. There is no one point on which his theories have been so much misunderstood. He believed that very noble incentives to duty and valuable helps in the formation of character were to be obtained from the wise study of the laws of our own being, and the structure of human society; and his chapter on "Moral and Religious Training through Science"—one of the most original and valuable in the book—is full of wise suggestions and of interesting examples. "The Ten Commandments," he would say, "are as clearly inscribed in the nature and constitution of man as on the tables of stone delivered to Moses." To him the revelations of Divine will and of the nature of human responsibility conveyed to us in science and in the order of nature were as sacred as the teachings of religion, were indeed a substantial part of religion itself. It must be owned that this is a doctrine which has not met with universal acceptance, and the exposition of which in Combe's writings is yet deserving of study. And in like manner his views on the training of children for the duties of citizenship, on a more rational system of teaching for girls, and on the necessity for instructing the teachers of the people in the art and mystery of their profession, were generally right and often profound; and possess hardly less value for this generation than for his own.

Yet it must be admitted that although Combe saw clearly and expounded forcibly some useful truths, he was not distinguished by much breadth of vision; and he certainly did not excogitate a full or philosophical system of education. He believed it possible by pure deduction to evolve a practical scheme from certain scientific principles; and there is evidence throughout the whole of his writings that he attached too little value to the lessons of actual experience, and that a fuller knowledge of child-nature, and of the practical working of schools would have rectified many of the deductions to which he attached most importance. He habitually depreciates the study of language, and repeatedly contrasts what he calls "real" knowledge with linguistic study, to the disparagement of the latter. To him words were mere means of expression and of communication. He never recognised the truth that words are the instruments as well as the representatives of thought; and that the right study of words and their relations is a discipline in logic and one of the most effective means of widening the range of a pupil's intelligence. Nor in his scheme of study was there much room left for history, for poetry, or for literary culture in any form. "*Res, non verba, quæso,*" was his favourite motto; yet it is not too much to say that his conception both of things and of words and of the part they should play in education was inadequate and unsound. And as to his system of phrenology, which he had learned from Spurzheim, and from which he hoped so much as an instrument for the regeneration of society, we must admit that it is now universally discredited by men of science; and that it betrayed Combe into a false method of psychological analysis. He believed that every separate moral propensity or mental gift had its own *habitat* in the brain, and was capable of being separately handled and developed. He thought that it would be enough to show a child that he was deficient, *e.g.*, in the organ of veneration, and then to set him to cultivate that faculty by placing before him appropriate objects for its exercise, and so to restore the balance of his character. Experience however has not confirmed this theory. It may well be doubted whether character has ever been fashioned in this conscious and mechanical way. At all events it does not appear even in this book, that the theory has ever been seriously carried out in practice; or that any one even of Combe's most enthusiastic disciples has accepted it as a working hypothesis, or applied it with success in the government, either of a school or of a home. There can be little doubt that Combe's faith in what he called phrenological science and his constant use of its terminology, vitiated many of his speculations about teaching, and prevented him from arriving at a full or satisfactory solution of the problem he desired to solve.

Few persons are better qualified than the editor of this volume to aid the public in discriminating what is ephemeral and obsolete in Combe's teaching from that which is likely to possess permanent value. This task, however, Mr. Jolly has not achieved and has scarcely attempted. And even those who most appreciate the importance of Combe's contributions to educational science will be fain to own that the bulk of this book is seriously disproportioned to the worth of its contents; and that a more valuable boon to the teacher's profession, and a far worthier and more enduring memorial of Combe himself might easily have been comprised in a volume of one-third of its size.

THE CAPERCAILLIE IN SCOTLAND

The Capercaillie in Scotland. By J. A. Harvie-Brown, F.Z.S., Member of the British Ornithologist's Union. (Edinburgh: David Douglas, 1879.)

THE introduction of birds into countries far from their original homes and their successful "acclimatisation" therein—to use a word now generally in vogue—is well known to have been accomplished in many instances—not always, however, to lead to the benefits expected to result from it. Thus the European house-sparrow has been transplanted to the United States of America, and is now a familiar bird of many of the great cities of the New World; the Indian grakle is at present one of the commonest birds in Mauritius, and in some of the Hawaiian Islands the native birds are said to have almost entirely disappeared in the course of their struggles for life with introduced species. But the *re*-introduction of a bird into a country where it has formerly flourished and where it has only recently—almost within the memory of man—become extinct, is, so far as we know, almost an unparalleled fact, and one that is well worthy of an accurate record.

Such has been the case in our own islands with one of the finest and largest species of game birds commonly

known as the capercaillie, or cock of the woods—the *Tetrao urogallus* of naturalists—and Mr. Harvie-Brown tells us the story of its extinction and revival in the interesting volume now before us.

The capercaillie, as Mr. Harvie-Brown after much discussion, decides that the name is most correctly written, was certainly a not unfrequent denizen of the pine-woods of Scotland and Ireland in former days, but, for some not yet clearly understood reasons, became gradually rarer in both countries, and according to the best evidence was finally extinct between the years 1745 and 1760, although there are several records of its alleged occurrence in Scotland at a later date, which Mr. Harvie-Brown considers "at least worthy of notice." In 1807 a capercaillie is said to have been shot in the Camus-na-gaul woods opposite Fort William, but this must have been the last survivor of the ancient race, for it is allowed on all sides that at the beginning of the present century the capercaillie could no longer be reckoned as an existing "British bird." Its reintroduction was effected by the late Marquis of Breadalbane in 1837 and 1838, after several ineffectual attempts. Living birds obtained in Sweden through the instrumentality of Sir Thomas Fowell Buxton and by the energy of Mr. Lloyd, the well-known Swedish sportsman and naturalist, were transported to this country and safely delivered at Taymouth under the care of English gamekeepers. About forty-eight individuals were imported in these two years, some of which were turned out, while others were kept in captivity for breeding purposes. So well did they succeed that in 1862 or 1863 their numbers on the Breadalbane estates were estimated to be at least 1,000, whilst according to other accounts they reached at this period to over 2,000 in number. From the Taymouth woods the capercaillies spread gradually over the adjacent districts of Central Scotland, wherever fir-woods prevailed suitable to the habits and food of the bird. Mr. Harvie-Brown gives us details of their first appearance and present numbers on various estates in Perthshire, Forfarshire, Fife, Kinross, Clackmannan, and Stirling, besides other outlying counties. A neatly executed map enables us to realise at one glance the statistics that Mr. Harvie-Brown has so diligently collected. "The capercaillie then," he concludes, "has populated the woods and forests of part of Scotland principally by its own exertions, since the great restoration at Taymouth; but there are certain minor centres of introduction which have undoubtedly added *some* impulse to their advance, though perhaps not to any extent compared with the impulse from the great centre." All naturalists must, we are sure, feel indebted to Mr. Harvie-Brown for the pains he has taken in investigating this interesting subject, and will congratulate themselves upon the restoration of this noble species to the British avifauna.

OUR BOOK SHELF

San Remo and the Western Riviera, Climatically and Medically Considered. By Arthur Hill Hassall, M.D. (London: Longmans and Co., 1879.)

DR. HASSALL has written a really useful work on a part of the Italian coast possessing many points of interest, more especially to those affected with chest diseases. He himself has spent two winters in the Western Riviera, and during that period has diligently collected information by personal observation and otherwise on the spot. Partly in this way, and partly by consulting authorities on the topography of the district, and with the help of specialists in various departments of natural history, Dr. Hassall has compiled a work which may be taken as a full and trustworthy guide by all who wish to visit the Riviera either for pleasure or health. There are a few attractive illustrations and a good map.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

An Index to Zoological Genera

THE Smithsonian Institution at Washington will publish at an early day an index, in one alphabet, to all genera hitherto proposed in zoology, whether for recent or fossil animals. It is to be based upon the "Nomenclators" of Agassiz and Marschall and the indexes to the *Zoological Record*. The name of the genus will be followed by the name of its proposer, the order to which it is referred, the date of its publication, and the symbols **A.**, **M.**, **Z.**, or **App.** (to indicate that a full reference may be found in [**A.**] Agassiz's "Nomenclator," [**M.**] Marschall's "Nomenclator," [**Z.**] the *Zoological Record*, or [**App.**] the Appendix to the proposed work), thus:—

Donachlora, *Sodoffsky*, Mamm., 1837, **A.**
Dorcasia, *Gray*, Gaster., 1847, **M.**
Loganius, *Chapuis*, Coleopt., 1869, **Z.**
Periplacis, *Geyer*, Lepid., 1837, **App.**

Names to which objection has been raised will be prefixed by an asterisk.

The appendix referred to will record in greater detail names which have been overlooked in the lists above mentioned, or have been published since 1877, the year reviewed in the last *Zoological Record*.

The object of this communication is to invite *at once* from European zoologists, and especially from palæontologists, lists of such names as should appear in the appendix. Such names (including corrections of any kind to the text of Agassiz's or Marschall's Nomenclators) should be accompanied by the name of the proposer of the genus, full bibliographical reference, date, etymology, and the order of animals to which the genus is referable. *In the Index the name of the person furnishing the reference will also be added as its sponsor.*

Many American zoologists have promised their assistance, but it must be evident that a work so extensive and of such universal value can only be satisfactorily prepared by the aid of European naturalists. As it is expected that the MS. of the Index will be ready by December 1 next, friends of the plan are earnestly invited to communicate with the subscriber at the earliest possible day.

The Mineral Waters of Hungary

THE numerous mineral waters of Hungary, some of which are used as table-waters, while others are prized for their medicinal properties, are unfortunately very imperfectly known either to the scientific world or the general public, and, what is worse, many of the particulars which have been published about them are altogether incorrect and misleading.

There are a number of balneological works treating of the European mineral springs generally, which include descriptions of those of Hungary, but in almost all cases these descriptions are either obsolete or unreliable. That such incorrect statements should appear in the works of foreigners is perhaps excusable, when we consider the difficulties under which the authors must labour in seeking to obtain information upon the subject; but we may fairly expect that a work published in Hungary should be without any such serious errors. It is a most unfortunate

circumstance that a work bearing the title "Les Eaux Minerales de la Hongrie," published under the auspices of the Hungarian Commission of the last Paris Exhibition, and very extensively circulated by them, is found upon examination to be altogether unreliable in its information. In the interests of truth I feel called upon to point out to foreigners the unsatisfactory nature of this work. This condemnation of the work in question is borne out by the following facts:—The book enumerates less than forty per cent. of the localities in Hungary at which mineral springs occur, no fewer than a thousand of such localities being omitted. Perhaps it is by way of compensating for these omissions that the anonymous author augments his list by making two or three mineral springs out of one by not discriminating its synonyms, and also by enumerating others which have no real existence. In many cases the author has failed to indicate the localities to which his information refers, especially in those instances in which there are several places of the same name; and these difficulties are increased by the numerous typographical errors in the book. The analyses published in the work are of a very unsatisfactory character, for while more than one hundred of the most recent and valuable analyses are altogether omitted, others, which were made twenty or thirty years ago, and are therefore far less reliable, are included in it.

Although it cannot be expected that a large class of readers should take an interest in these details about the Hungarian mineral waters, yet I have thought it right to point out the unreliable character of this work in your widely-circulated journal, so that the errors should not be transferred to the pages of balneological works of a more general character. To the authors of such works I should be glad to furnish information concerning the mineral waters of this country, as it is a subject which I have made my especial study. J. BERNÁTH

Buda-Pest

Does Sargassum Vegetate in the Open Sea?

IT is related by Humboldt and Harvey that floating *Sargassum bacciferum* vegetates in the open sea, by sprouting branches without fructification, whilst other naturalists have seen in the yellowish floating pieces only the pale and altered dead remains of the plant. If these floating fragments were capable of vegetating, their branches should be brown or olive-coloured like living specimens on the rocks below water on the sea-shore, and if floating Sargassum really grow, fructification should not be wanting.

I have heard from several travellers, who have sometimes crossed the Sargasso Sea, that they, like me, never saw other than pale and dead floating sargassum, so that I believe those accounts of Humboldt and Harvey to be erroneous. Does any reader of NATURE know of living Sargassum in the open sea as a fact?

There exist many fanciful reports on Sargassum, *e.g.*, that some branches of the floating Sargassum rise two inches above water, and are thus driven along by the wind. Can any one confirm this? No botanist has hitherto observed it, and no sea-weed is known to behave thus. Haeckel and other learned men who never crossed the Sargasso Sea, speak of "a colossal sea-weed forest of 40,000 geographical square miles."

I would be greatly indebted for exact information as to the degree of density in which Sargassum has been observed. Although I was eleven days crossing in a steamer the two great seas containing Sargassum, I saw nothing at all in the Pacific on the direct route from San Francisco to Yokohama; and in the Atlantic I observed only single fragments from 50 to 100 feet apart; other credible travellers assure me of having seen the Sargassum sometimes almost grouped together in loose masses or strips of about 400 feet in length, hardly at all entangled and of no depth. I doubt therefore, also, whether Sargassum could hinder sailing vessels. OTTO KUNTZE

Leipzig-Eutritzsch, September 30

[In Dr. Kuntze's letter, vol. xx. p. 426, line 4, read: "In Eozöon they became;" line 31, "under red heat;" line 40, condensed, not into incandescent liquids, but into incandescent crystals; line 44, "granate" ("garnet," not "granite").]

A Liquid Rheostat

WHILE experimenting on resistance to the electric current, I have devised an instrument in which fluid is used to conduct the current under examination. This may perhaps be of use to some who are interested in this subject. The sketch, Fig. 1, shows the nature of the instrument. A B is a piece of elastic tube containing a weak solution of salt in water; this is held in the clamp C. By the screw D the tube can be compressed and its sectional area altered, and through this its resistance. G is the galvanometer and E the battery. Finding the instrument to

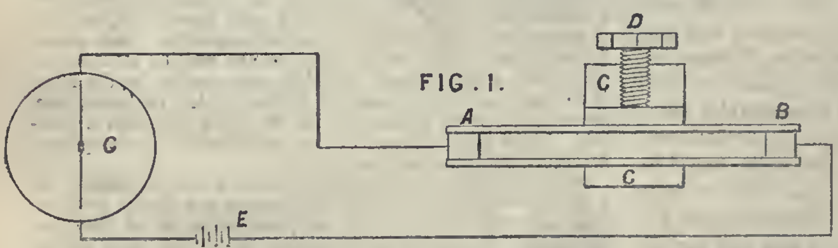

FIG. 1.

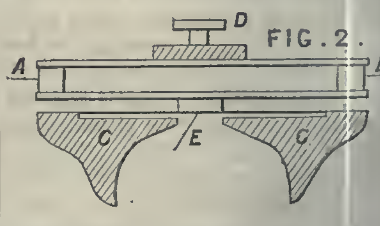

FIG. 2.

be very sensitive on a reflecting galvanometer I thought that probably the tube would be a means of transmitting articulate speech. I find this to be the case. Fig. 2, A B, elastic tube similar to the one used in the former instrument; C C, mouthpiece; E, disk, connected to the tube at E. A B is put in circuit with a telephone and battery; D, screw to regulate the pressure on the tube. I call the instrument, Fig. 1, a liquid rheostat.

Taunton, September 24 FREDERICK JOHN SMITH

The Carving of Valleys

MR. WALTER R. BROWNE tells us in NATURE, vol. xx. p. 504, that he has discovered in the valley of a highland burn evidence that "the agencies of 'sub-aërial waste' are seen to have worked their will for untold ages on the Cambrian sandstones of Glen Beansdale, and to have produced—nothing."

Without making any attempt to explain how the old river channel he describes is not "choked by the *débris* which has come down from its sides," further than to suggest that "the tiny runnel which now drains the gulley" may sometimes be, not the little streamlet which Mr. Browne saw, but a great roaring torrent quite capable of "direct erosion of its own, and of sweeping away the *débris*" which may have tumbled into it from its sides, it appears to me remarkable that evidence *against* sub-aërial denudation should be brought from the Scottish highlands where every mountain and valley seem to testify eloquently in its favour. I am pretty familiar with a great part of the northern highlands, and I do not remember a single mountain which does not bear on its flanks ample evidence of the energy of this form of erosion. It is now some years since I have been at Loch Maree, but if I am not greatly mistaken Ben Slioch itself is draped in loose angular fragments, the result of its own decay. If Mr. Browne, while in these regions, visited Glen Sligachan, in Skye, he must have found that wherever he walked in that wild valley, it was on fragments of rock that have not only slid down the mountain sides in vast torrents, but spread out over the whole floor of the glen, burying the original glaciated surface deep beneath them; and in all parts of the more southern and central highlands we find the same irresistible evidence of the continued waste of the hillsides by heat and cold and the rainfall.

As to the behaviour of streams in excavating valleys, very much depends upon the character and arrangement of the rocks over which the river flows; there are many streams in both

highlands and lowlands which in one part of their course have cut deep vertical gorges not unlike cañons, while at another they have scooped out wide open valleys with gently sloping sides, so to come to any conclusion based on the assumption that the eroding action of streams is uniform is very unsafe.

Mr. Browne seems also to take a very peculiar view of the extent of the ancient glaciers, as he speaks of the channel of the little stream he describes as "sufficient to guide the glacier in its flow," seeing that the great glacier which flowed over Scotland from north-west to south-east took no notice of such a channel in its course as the Firth of Tay, but swept over it and the county of Fife beyond, scarcely showing a trace of being deflected at all. Surely there could not be such an enormous difference in the dimensions of the glaciers on the opposite coast as this would indicate. Whatever was the case on Loch Maree, the glaciers that moved down Loch Assynt and Loch Broom were no pigmies.

JAS. DURHAM

Newport, Fife, September 27

The Bis-cobra, the Goh-sámp, and the Scorpion

SNAKES of all kinds are held in great horror by the natives of India, and they slay indiscriminately and ruthlessly all they come across, but this horror pales before the terror inspired even by the names of the bis-cobra and goh-sámp,—terror so great, that, if met with, the harmless animals are given the widest berth possible, and their destruction is never attempted. Though actual animals, they are virtually mythical, that is as regards the deadly properties assigned to them, and we easily recognise in them the originals of the flame-breathing dragon and deadly basilisk. The gaze of the bis-cobra is awful even from a distance and its bite is instant death; and if the goh-sámp breathes upon, or at you, you fall dead at once.

With such awful reputations attached to them, I lost no time, in my early career, in attempting to make the acquaintance of these formidable reptiles, and, after much labour, succeeded.

No one would help me in procuring a bis-cobra, and my servants repeatedly warned me against the risk and madness of the attempt. At one time I had engaged the services of a savage woodsman in collecting birds' eggs, and to him I, one day, applied for a bis-cobra, but he at first refused, and it was only the promise of large bakhsheesh that ultimately induced him to promise his assistance. After several days he appeared carrying an earthen pot at the end of a long bamboo, and meeting me, whispered mysteriously in my ear "Sahib! bis-cobra!" Glad of the news, I summoned my servants, who, when they heard the reason of the summons, reluctantly formed a distant semicircle. The pásee cautiously put down the pot and also retired to a distance. In no way dismayed, I approached the pot, removed the dirty rag around its mouth and looked in. As expected, I found a beautiful brown and yellow lizard, freely protruding in its fear a forked anguine tongue, and anxious to escape. On taking it up it seized my hand with its delicate teeth, and in this position I held it up to the horror-stricken servants who exclaimed in fear "Sahib! sahib! chōr do, pheak do (Master! master! let (it) go, throw (it) away)." Then, on my declining to do either, they, like the barbarians of old, waited anxiously to see whether I "should have swollen or fallen down dead suddenly," and, seeing no harm, they quietly dispersed.

My adventure with the goh-sámp was unsought and equally satisfactory.

Walking in my garden one day, I met the gardener running away with affrighted look from a pear tree, and asked the reason; he could only gasp out "Goh-sámp, sahib, goh-sámp!" and implore my return. Delighted at the opportunity, I pressed on, and soon saw the awful reptile trying to dodge my gaze; a large scaly, uncanny looking tree lizard about fourteen inches long. In the distance the mali (gardener) implored me to beware his "phoonk" (blast of breath), but I courted it, by trying to dislodge him, which I succeeded in doing by shaking the bough, and then he threw himself on the ground and scuttled up another tree. Both lizards are absolutely harmless, and I believe a poisonous lizard is quite unknown.

The scorpion is not dreaded like the snake, but, like it, is inevitably killed. Its habits and pursuits well deserve study; my observance of the former has enabled me to clear away (to my own satisfaction) many obscurities with regard to its poison weapon and the mode of using it. And let me declare at once that the popular idea regarding scorpionic suicide is a delusion based on impossibility. Owing to the position and nature of its weapon, the animal cannot strike itself. It does not protrude a sting as bees, *et hoc genus omne*, do, and the line of strike is downwards and backwards, with at times a lateral but yet downward motion. As literally described in Holy Writ, *it strikes but does not sting;* and its motion in so doing may be imitated by seizing the tip of the index or middle finger with the thumb, and suddenly liberating the former.

The poison is acid and albuminous; the latter I presume, as on placing a living specimen in spirit, the animal in its death throes ejected it, and it immediately coagulated in threads.

The pain and constitutional disturbance attendant on scorpion strike are often very severe, and children have occasionally succumbed; but adults only complain of the pain, which generally passes off in half-an-hour. On two occasions I have passed through a host of migrating crickets, once by day and once by night; on the first occasion my carriage wheels crunched for a mile through a cricket migration; and on the second my palkee bearers' feet slid about amid crushed crickets; on this occasion one of the bearers yelled out that a scorpion (out on a cricket spree) had struck his foot, and hobbled up to the palkee. Having the means at hand I applied a paste of ipecacuanha and laudanum, with almost immediate relief, and the bearer trudged on with the rest.

Peshawar H. F. HUTCHINSON

Certain Animal Poisons

I HAVE had unpleasant experiences of the poisonous properties of the Portuguese man-of-war, the great hornet, and the centipede.

While bathing at the Cape as a boy I managed to get the long lovely blue tentacle of the first round my wrist, and well recollect the attendant long-enduring agony and irritation, while the blue mark remained long on my wrist. Twenty-five years after, while soaking in a P. and O. steamer's marble bath in Madras roads, I suddenly received what seemed an agonizing stab below my left knee, and jumped out of the bath with the pain. The cause was at once apparent, a bit of the fatal blue filament had been pumped into the bath, and left the familiar mark on my knee, and I bore it for a long time.

On one occasion I was showing some friends over the famous "Arrah House" and opened a small window to let in more air and light; in doing so, I unwittingly disturbed the adhesions of a great hornet's nest, and one of the infuriated inmates at once stung me on the left temple; the pain was intense and the swelling immediate; aware of the constitutional disturbance which would follow, I made for home (about 500 yards distant), and reached the threshold of my drawing room, and there I was brought to an instant standstill, unable to move hand or foot, and trembling like an aspen leaf. I was laid on a sofa, and asked for a glass of port wine, which soon revived me.

This dreadful hornet, nearly two inches long, deep brown with a broad yellow band across the abdomen, builds large globular paper nests, and is not rare in the Himalayas, where it may often be seen in the pines. The hillmen dread it extremely, and with good reason, for a swarm, or even a few individuals will attack you fiercely and follow you for miles.

Griffs, who have fired at a nest, against the remonstrances of their hillmen, have paid dearly for their rashness. When attacked, the hillmen squat down and drawing their blankets closely around them, await the subsidence of the storm, rarely escaping two or three stings. I have known *one* of these hornets kill a child by its sting; and many horses have been destroyed by an infuriated swarm. These are the dreadful animals which assisted in the expulsion of the Amorites of old.

The common bee, which in India often builds in trees and ruins, frequently attacks men and horses, irritated by the smoke of the fires (for cooking) lighted under the trees or in the buildings, and a general *sauve qui peut* is the only mode of escape.

Many ludicrous adventures occur from this cause out here, and I will describe a recent one. The officers of a British regiment stationed at Umballa were dressing for Sunday morning Church parade, when the alarm was given in the compound of three who lived together, that the bees were abroad. As escape from the parade was impossible, and the infuriated bees had to be faced, the three griffs made a syce (horse attendant) envelope himself in a blanket, while each wrapped a sheet around himself, and then formed a line, the front officer holding on to the syce's bamboo, and the other two to one another's swords, and in this guise they groped their way out of the compound surrounded by

the angry bees; cautiously emerging from their sheets on the high road, the first person they encountered was their Colonel and his family driving to Church. The finale may be imagined!

I have always been fond of sleeping out during the hot weather, *sub Jove frigido*, or rather *torrido*, and used to have a sooráee (a porous earthen water bottle) capped by a tumbler, on the ground by my side.

One night I awoke to drink and, half awake, lifting the sooráee on to my naked knee proceeded to fill the tumbler. In a moment I felt as if a red hot poker had been freely applied to my knee, and, thinking that I had been stung by a snake, rushed into the house for a light, and a dose of sal volatile. I was now wide awake, and returned with the light to examine into matters, and then I found a large centipede coiled round the bottom of the sooráee, whither it had come for coolness or a drink, or both. It was six inches long. Judging from the size of the burn (for I bore the large red mark for many days), I inferred that I had not been bitten, but that the whole animal was acrid.

Spider's Web, New Caledonia

CONSUL LAYARD's account of the spiders' webs of the Polynesian Arachnids (NATURE, vol. xx. p. 456) reminds one of the colonial enthusiasm of certain fair ladies in Mauritius seventy years ago, previous to the capture of that island by General Abercrombie.

Throughout the Mascarene group are numerous species of *Araneideæ*, among which *Epeira inaurata* and *E. mauricia* are pre-eminent, their bright yellow webs being conspicuously stretched between the pointed leaves of the agaves and prickly-pears. Taking advantage of these "grandes toiles verticales à fils jaunes, soyeux et susceptibles d'être travaillés; sous le gouverneur-général Decaen, les dames créoles de l'île de France tissèrent avec les fils de ces belles aranéides une paire de gants dont elles firent hommage à l'impératrice." Change of Colour in Frogs

CAN any of your readers tell me if it is a fact that frogs change their colour before a change takes place in the weather?

A few days ago I was told at a village in Worcestershire, during heavy rain, that it would be fine to-morrow because a frog had been seen turning yellow. The fine weather came. I was informed that frogs become dark-coloured before wet weather sets in. W. J. CHAMBERLAYNE

Junior United Service Club, September 30

["The changes which the colour of the frog undergoes both in intensity and hue from the *variation of temperature, the presence and absence of light* . . . although certainly much less striking and considerable, are *scarcely less varied* than those exhibited by the chameleon."—Bell, "British Reptiles."]

SUBJECT-INDEXES TO TRANSACTIONS OF LEARNED SOCIETIES[1]

WE all remember the excellent paper read at the Oxford Conference by Mr. J. B. Bailey, sub-librarian at the Radcliffe Library, upon the advantage of a subject-index to scientific periodicals. Mr. Bailey spoke with just praise of the splendid alphabetical catalogue issued by the Royal Society, but observed that from the nature of the case this is "nearly useless in making a bibliography of any given subject, unless one is familiar with the names of all the authors who have written thereon." This is manifestly the case. As an illustration both of the value and the deficiencies of the Royal Society's index, I may mention that while on the one hand it has enabled me to discover that my father, chiefly celebrated as a philologist, has written a paper on the curious and perplexing subject of the formation of ice at the bottoms of rivers, the existence of which was wholly unknown to his family, it does not, on the other hand, assist me to ascertain, without a most tedious search, what other writers may have investigated the subject, or consequently how far his observations are in accordance with theirs. Multiply my little embarrassment by several hundred thousand, and you will have some idea of the amount of ignorance which the classified index suggested by Mr. Bailey would enlighten. We may well believe that the only objection he has heard alleged is the magnitude of the undertaking, and must sympathise with his conviction that, granting this, it still ought not to be put aside merely because it is difficult. I hope to point out, however, that so far as concerns the scientific papers, to which alone Mr. Bailey's proposal relates, the difficulty has been over-estimated, that the literary compilation need encounter no serious obstacle, and that the foundation might be laid in a short time by a single competent workman, such as Mr. Bailey himself. Of an index to literary papers I shall speak subsequently; and, there, I must acknowledge, the difficulties are much more formidable. But as regards scientific papers, it appears to me that the only considerable impediment is the financial. When the others are overcome, then, and not till then, we shall be in a favourable position for overcoming this also. The reason why the formation of a classified index to scientific papers is comparatively easy, is that the groundwork has been already provided by the alphabetical index of the Royal Society. We have the titles of all scientific papers from 1800 to 1865 before us, and shall soon have them to 1873. Though it might be interesting, it is not essential to go further back. We have now to consider how best to distribute this alphabetical series into a number of subject-indexes. To take the first step we merely require a little money (the first condition of success in most undertakings), and some leisure on the part of a gentleman competent to distinguish the grand primary divisions of scientific research from each other, and avoid the errors which cataloguers have been known to commit in classing the star-fish with constellations, and confusing Plato the philosopher with Plato a volcano in the moon. I need only say that very many of our body would bring far more than this necessary minimum of scientific knowledge to the task. I may instance Mr. Bailey himself. The money would be required to procure two copies of the alphabetical index (which, however, the Royal Society would very likely present), and to pay an assistant for cutting these two copies up into strips, each strip containing a single entry of a scientific paper, and pasting the same upon cardboard. It would be necessary to have two copies of the alphabetical catalogue, as this is printed on both sides of the paper; and as the name of the writer is not repeated at the head of each of his contributions, and would therefore have to be written on the card, close supervision would be required, or else a very intelligent workman. When this was done, the entire catalogue would exist upon cards, in a movable form instead of an immovable. The work of the arranger or arrangers would now begin. All that he or they would have to do would be to write somewhere upon the card, say in the left hand upper corner, the name of the broad scientific division, such as astronomy, meteorology, geology, to which the printed title pasted upon the card appertained, and to put each into a box appropriated to its special subject, preserving the alphabetical order of each division. We should then have the classed index already in the rough, at a very small relative expenditure of time, money, and labour. For the purposes of science, however, a more minute subdivision would be necessary. Here the functions of our Council would come into play, and it would have a great opportunity of demonstrating its usefulness as an organising body by inducing, whether by negotiation with individuals or with scientific corporations like the Royal Society, competent men of science to undertake the task of classifying the papers relating to

[1] By Richard Garnett, Superintendent of the Reading Room, British Museum. Read at the March monthly meeting of the Library Association of the United Kingdom. Contributed by the Author.

their own special studies. Men of science, we may be certain, are fully aware of the importance of the undertaking, which is indeed designed for their special benefit; and although they are a hard-worked race, I do not question that a sufficient number of volunteers would be forthcoming. When one looks, for example, at the immense labour of costly and unremunerated research undertaken by a man like the late Mr. Carrington, one cannot doubt that men will be found to undertake the humbler but scarcely less useful and infinitely less onerous task of making the discoveries of the Carringtons generally available. I am sure, for instance, that such men as Mr. Knobel and Mr. Carruthers would most readily undertake the classification of the astronomical and the botanical departments respectively, provided that their other engagements allowed, as to which, of course, I cannot affirm anything. Supposing our scientific editors found, they would proceed exactly in the same manner as the editor who had already accomplished the classification in the rough. Each would take the cards belonging to his own section, and would write opposite to the general subject title written by the first classifier the heading of the minor sub-section to which he thought it ought to be referred; thus, opposite Botany—Lichen, and so on. He would then put the title into the box or drawer belonging to its sub-section, and when the work was complete we should have the whole catalogue in a classified form, digested under a number of sub-headings. Some preliminary concert among the scientific editors would, no doubt, be necessary, and a final revision in conformity with settled rules. It might be questioned, for example, whether a dissertation on camphor properly belonged to botany, chemistry, or materia medica; whether the subject of the gymnotus was ichthyological, anatomical, or electrical; whether in such dubious cases a paper should be entered more than once. It would save time and trouble if these points could be determined before the classification in the rough was commenced; in any case considerable delay from unavoidable causes must be anticipated. It is to be remembered, on the other hand, that the work could, under no circumstances, be completed until the publication of the Royal Society's alphabetical index of papers from 1865 to 1873 was finished, which, I suppose, will not be the case for two or three years. There will, therefore, be sufficient time to meet unforeseen causes of delay. If the classified index could be ready shortly after the alphabetical, if we could show the world that the work was not merely talked about as desirable, but actually done in so far as depended upon ourselves and the representatives of science; that it already existed in the shape of a card catalogue, and needed nothing but money to be made accessible to everybody—then we should be in a very different position from that which we occupy at present. I cannot think that so much good work would be allowed to be lost. The catalogue, not being confined to papers in the English language, would be equally useful in every country where science is cultivated, and would find support all over the civilised world. Either from the Government, or from learned societies, or the universities, or the enterprise of publishers, or the interest of individual subscribers, or private munificence, means would, sooner or later, be forthcoming to bring the work out, and thus erect a most substantial monument to the utility of our Association. It would obviously be important to provide that scientific papers should be indexed not only for the past, but for the future. If, as I trust, the Royal Society intends to continue the publication of its alphabetical index from time to time, the compilers of the classified index will continue to enjoy the same facilities as at present. There must be some very effectual machinery at the Society for registering new scientific papers as they are published. What it is we may hope to learn from our colleague, its eminent librarian, who must be the most competent of all authorities on the subject. Mr. Bailey draws attention to several scientific periodicals as useful for bibliographical purposes, and I may mention one which seems to be very complete.[1] It is published at Rome. The number for last December, which I have just seen, is so complete that, among a very great number of scientific papers from all quarters, it records those on the telephone and the electric light, in the "Companion to the British Almanac," which, I think, had then been only announced here, not published, omitting the other contributions as non-scientific. It further gives a complete index to the contents of the *Revista Cientifica*, a Barcelona periodical, which had apparently just reached the editor, from its commencement in the preceding April. By this list I learn that the electric pen, the subject of our colleague Mr. Frost's recent paper, had been the theme of a communication to a Barcelona society in May last. It certainly seems as if any library that took this periodical in, and transcribed the entries in its bibliographical section on cards properly classed, would be able to keep up a pretty fair subject-index to scientific papers for the future. I must, in conclusion, say a few words on a subject-index to the transactions of literary societies. The prospect is here much more remote, from the want of the almost indispensable ground-work of a general alphabetical index. We have seen what an infinity of trouble in collecting, in cataloguing, and in transcribing will be saved by the Royal Society's list in the case of scientific papers, and are in a position to appreciate the impediments which must arise from the want of one in this instance. The work could be done by the British Museum if it had a proportionate addition to its staff, or by a continuance of the disinterested efforts which are now devoted to the continuation of Mr. Poole's index to periodicals. Failing these, the most practical suggestion appears to me Mr. Bailey's, that the undertaking might be to a considerable extent promoted by the respective societies themselves. If the secretaries of the more important of these bodies would cause the titles of the papers occurring in their transactions to be transcribed upon cards and deposited with this Association, we should accumulate a mass of material worth working upon, and which might be arranged while awaiting a favourable opportunitity for publication. In some instances even more might be done. The library of the Royal Asiatic Society, for example, contains not merely its own transactions, but those of every important society devoted to Oriental studies, as well as all similar periodicals. Our friend, Mr. Vaux, could probably, in process of time, not only procure transcripts of the papers contained in these collections, but could induce competent Orientalists to prepare a scheme of classification, and such a classified list, complete in itself and of no unwieldy magnitude, could be published as a sample and forerunner of the rest. The initiative in such proposals, as well as those referring to scientific papers, should be taken by our Association, which can negotiate with eminent men and learned bodies upon equal terms, and speak with effect where the voice of an individual would be lost. The desideratum of a classed index, in a word, affords our Society a great opportunity of distinguishing itself. It is this aspect of the matter, no less than the importance of the matter itself that has encouraged me to bring it under your notice.

ON VARIABLE STARS

IT had long been known that certain stars greatly varied in brightness and some observations had been made concerning them, but it was reserved to the Herschels to pave the way for practical investigators. Notwithstand-

[1] *Bullettino di bibliografia e di storia delle scienze matematiche e fisiche.* Pubbl. da B. Boncompagni; Rome, 1868, &c.

ing the importance of the results which the observation of them bids fair to offer concerning the nature of the sidereal universe, the variable stars have not attracted so much attention as other even less important phenomena in the starry heavens, and one cause of this must be sought in the circumstance, that most of these observations are best made with very small telescopes or even with the naked eye, and while it is the duty of the professional astronomer to make use of the expensive instruments, of which he has charge, the inclination of the amateur astronomer in this country often leads him in the same direction. However, the attention of those who take an interest in the science but cannot afford a large outlay, cannot too often be urged towards this kind of observation, that while it so much needs their help is so thoroughly within their reach.

The best method is due to Argelander, a follower of Bessel, who was considered the first authority on the subject during his lifetime. It was propounded in his "Aufforderung an Freunde der Astronomie zur Anstellung von eben so interessanten und nützlichen, als leicht auszuführenden Beobachtungen über mehrere wichtige Zweige der Himmelskunde," which appeared in Schumacher's *Jahrbuch für* 1844, a periodical seldom met with in this country, which may in a measure explain the comparatively little attention that has been given to this subject on the part of British amateurs, who have so energetically followed up more complicated investigations. The success of those who have spent even a short time on these observations may be considered a sufficient appeal, and we venture to hope that the following short sketch of the easiest and most convenient method will be acceptable to some of the readers of NATURE who have not Argelander's lengthy paper at hand. The observations are in reality far simpler than the description of them looks. The stars visible to the naked eye are arranged in six classes according to their brightness, but it is often doubtful to what magnitude we shall refer an object, because we are able to judge about much smaller differences than those that distinguish two magnitudes, the number of which is therefore too small. The smallest difference perceptible to the average sight is a tenth of a magnitude, and we are therefore able, by a method of sequences, to reach a considerable accuracy. Researches on variables have further this advantage that we do not want to know the absolute magnitude but only the brightness relatively to certain other stars. These comparison-stars must be chosen with intervals of not above a half magnitude, and be situated as near the variable as they can be had, for the transparency of the air is often different not only in different altitudes, but also in different azimuths—nay even owing to aqueous vapour and chemical causes at times in the same place. Observations near the horizon should be avoided, and near the zenith the position is difficult. Twilight, moonlight, and lamplight would likewise interfere, and above all it must be avoided to observe from a lighted room. Against the moon or a distant gas-lamp in a town a screen can be used. If clouds are near they will render the comparisons uncertain. Cirro-stratus commencing to descend from high in the atmosphere is particularly deceiving. The estimation of stars of the first magnitude is difficult, and an evenly illuminated background in this case rather an advantage, or a slight fog, but in the latter case and when detached clouds are on the sky the observations have to be repeated with an interval of a few minutes, because fogs are rather irregular; at other times an observation may be secured in a few minutes, and more observations the same night are only required in case of quickly changing stars. They generally give identical results, but two or more observers are an advantage, though their estimations may have constant differences, because various colours affect individual eyes differently. No attempt need be made to look simultaneously at both stars, because the sensibility of the eye in different spots is different, and this error would not be eliminated. Look first at one star, then turn quickly to the other, look at that and return to the first again. It is well to turn the eye a little to the side, when watching a star. It appears then brighter, because the middle of the retina is tired with constant work. The comparison of stars barely visible is to be avoided. The results, together with the nature of the circumstances, should be noted at once, and in the dark. It will be remarked that the causes of error, referred to above, are not sensibly removed by using photometers, and other errors may be introduced by such complicated apparatus. Faint stars may be observed through a binocular. The glass used should be colourless, always the same, and the distance between the eye-glasses carefully adjusted. It must be confessed that this kind of work cannot be carried out in places where the sky does often not clear for months, as in North-West Ireland; on the other hand the English climate seems favourable. It is often blue sky, if only partly, and no superior definition is required. At present this part of astronomy is mainly dependent upon the labours of Julius Schmidt, of Athens. Some knowledge of the constellations is necessary, and that may be gained from Argelander's or Heis's Uranometries. In case the research be extended to telescopic stars Argelander's large atlas should be procured. It is known that Pogson at Hartwell and Madras has made diagrams of stars round the variables, which would be very useful.

The differences are noted in "steps," each of which is equal to a tenth of a magnitude. If the comparisons are doubtful but most give one star, a, larger than another, b, it is said that a is one step above b : $a\,1\,b$. If at all times a seems larger than b, it is two steps above it : $a\,2\,b$. If the difference is remarked at a glance, a is three steps above b : $a\,3\,b$. Still greater difference is denoted $a\,4\,b$, which is occasionally used, though so great a difference cannot be estimated so exactly as a smaller one, the probable error of which is much below one step, so that it is preferable to give the comparisons in half steps. For exercise Argelander's comparison stars can be used from "Astronomische Beobachtungen auf der Sternwarte zu Bonn," vol. vii., 1869. The steps might not be exactly identical in all cases, but they ought not to deviate much. The variable should not only be compared with the greater and smaller star but also with the mean of them, which is very accurate. From each comparison follows then the brightness of the variable, and the average of these is taken first in the common manner, next allowing weights inversely proportional to the number of steps, and the means of the two is assumed as the definitive result. Of course this is more estimated than computed, and the two results agree generally.

From magnitudes thus obtained in a scale of steps the epochs of maxima and minima are next sought, from which follows the period, which is the principal element. When a sufficient number of periods are available it can be seen whether this is constant, and if not, one must try to find a formula which will give the length at any time. A good many periods are about 300 days, but many only a few days. The brightness in the two principal phases will generally be found irregular if the period be so. Some stars have more than two maxima and minima during the same period. Next we project on a paper ruled in squares the brightness of the variable with the time as abscissa, counted from the nearest preceding maximum and expressed in parts of the respective period. The curve drawn as nearly as possible through the points, whose weights may be indicated by circles round them, is called the light curve, and on that we can read off the brightness for any moment, but it is not always possible to treat the observations thus *en masse;* sometimes single periods have to be separately discussed, and indeed when it is great we can arrive at some results from a single

period, but if it is short many revolutions must be watched. These stars proceed more quickly from minimum to maximum than from maximum to minimum, and this is also the case with new stars. At last it is found that the colour is most monochromatic nearest the minimum. The brightness of the comparison stars is best obtained from their comparison with the variable and become therefore better known the more revolutions are watched. The final discussion will sometimes show that one or more of the comparison stars are variable themselves, for astronomers agree that there are many more variable stars in the sky than those contained in the catalogues.

As to the physical explanation of these phenomena we do not learn much from Argelander, who was one of the last champions of the old school. It is even said about him that he to the last stuck to Herschel's theory of the structure of the sun in spite of this being opposed to Newton's axioms, and framed, according to the now obsolete assumption, that every heavenly body ought somehow to furnish a comfortable abode for beings like ourselves. We can only comprehend unknown things from what is already known to us, and it is therefore rational to suppose variable stars analogous to our sun, whose lustre must vary with the extent of its spots. It is no doubt reserved to the spectroscope to settle the question, meantime we can only keep in view Hind's important remark that variable stars are often of a ruddy colour, and appear surrounded by nebulosity at their minimum. W. D.

COFFEE-LEAF DISEASE OF CEYLON AND SOUTHERN INDIA

1. *HISTORICAL REMARKS.*—During the last ten years, the coffee plantations of Ceylon and Southern India have had to contend with a disease which has seriously affected their productiveness and entailed a heavy loss upon the proprietors. This disease, *Hemileia vastatrix*, popularly known as the coffee-leaf disease, was first observed in May, 1869, on a few plants in Madulsima, a newly-opened coffee district in the south-west of Ceylon, bordering on the low country. In July following, two or three acres were attacked, and from that time the disease has gradually spread, till, in 1873 all, or nearly all, the estates in the island were attacked by it. On the appearance of the disease in 1869, the distinguished fungologist, the Rev. M. J. Berkeley, determined its true character, and described it in the *Gardener's Chronicle* for 1869 (p. 1,157, with woodcut). It was found to be a fungus allied to the moulds, and named *Hemileia vastatrix*, B. and Br. It was subsequently described in the *Journal* of the Linnean Society ("Botany," vol. xiv. p. 93, pl. 3, Fig. 10), and a short notice appeared in the *Quarterly Journal of Microscopical Science*, 1873, pp. 79-81. In 1876 Dr. M. C. Cooke described and figured the disease from Indian specimens in the India Museum Report, 1876, pp. 4-6. More recently the Rev. R. Abbay, who, during several years residence in Ceylon, made this disease an object of special study, gave a fuller description of it, with the results of his observations upon the germination of the spores and their growth under artificial cultivation, in the *Journal* of the Linnean Society, 1878 ("Botany," vol. xvii. pp. 173-184, pl. 13 and 14).

In his first notice of the disease the Rev. M. J. Berkeley speaks of it as a "minute fungus which has caused some consternation amongst the coffee planters of Ceylon in consequence of the rapid progress it seems to be making amongst the coffee plants." He further remarks: "It is not only quite new, but with difficulty referable to any recognised section of fungi. Indeed, it seems just intermediate between true mould and Uredos, allied on the one hand to *Trichobasis*, and on the other to *Rhinotrichum*. Though the fungus is developed from the parenchyma of the leaf, there is not any covering to the little heaps, such as is so obvious in *Uredo* and its immediate allies, while the mode of attachment reminds one of *Rhinotrichum*." At that time no other form of *Hemileia* was known, and it was supposed to stand alone as the only species, and to be indigenous to Ceylon. Since then, another species of *Hemileia*, viz., *H. canthii*, B. and Br., has been found on a Ceylon jungle tree, *Canthium campanulatum*,[1] and lately Dr. Cooke appears to have met with a third species from Southern Africa.

Writing in 1874, Dr. Thwaites, the distinguished Director of the Botanic Gardens, Ceylon, describes the *Hemeleia vastatrix* as "a parasitic growth within the coffee tree of a well-defined species of fungus, originated and reproduced by means of spores, easily distinguished from every other known fungus." "There can be no question," he continues, "that this fungus is communicated from coffee plant to coffee plant through the dissemination of its spores, and that these may be conveyed by the wind, or by streams of water, or by animals of any kind moving from place to place." Though at first it was believed that some elements of the fungus were present "in the growing tissues of the coffee plant in a *diffused form*," this view was afterwards abandoned, further microscopical investigations having proved that the disease was mainly external, and "that the coffee tree suffered rather from exhaustion than from the poisoning of its juices." During 1873 and 1874 investigations of an important character were carried on by Dr. Thwaites and the Rev. R. Abbay, which led them to the conclusion that when grown upon charcoal kept constantly moist, the orange-coloured spores representing the fruit of the disease, gave rise to filaments more or less branched. At the termination of the branches "*secondary spores* appear to have been produced in the form of radiating necklace-shaped strings of little spherical bodies of uniform size, closely resembling the fructification of an *Aspergillus*."

2. *Effects produced.*—The effects of the fungus upon the coffee trees would seem to be the gradual loss of vital energy caused by repeated destruction of the leaves. The tree after the first attack of the disease, which is often apparently the most severe, throws out fresh, healthy-looking leaves, and exhibits for a certain period the appearance of having perfectly recovered. These fresh leaves, however, after the expiration of a few months, exhibit the characteristic spotting, and are sooner or later covered, on the under side, by orange-coloured dust representing the spores of the disease, and, as in the previous attack, fall prematurely. These repeated attacks at length seriously affect the health of the tree, which, if old and ill-cultivated, becomes of little or no value as a crop-producer.

The rapidity with which the disease was propagated after its first appearance, may be realised from the fact that although it was noticed only in one locality in May, 1869, it quickly spread to the neighbouring coffee-districts, and especially among native coffee, till in 1873 it was spoken of "as being found in nearly all, if not all, the estates in the island." The disease appears to have been noticed in India in 1869 and 1870, almost simultaneously with its appearance in Ceylon.[2] In February, 1874, its presence was seriously felt in Tellicherry, and it appears to have spread generally through the Wynaad and Mysore districts, and its first effects were so severe that it threatened to give a considerable check to coffee enterprise in Southern India.[3] In 1876 the disease appeared in Sumatra, and this year it has been found in the plantations of Java and Bencoolen; there can be little doubt, therefore, that the *Hemileia* is destined to be a wide-spreading and prevalent enemy in all coffee-producing areas of the East Indies.

The effects of the leaf-disease upon the exportation of

[1] "Enum. Plant. Zeylan. Rublaceæ," p. 153.
[2] Report of India Museum, M. C. Cooke, 1876.
[3] *Gardener's Chronicle*, February, 1874.

coffee from Ceylon, may be very distinctly traced. In 1869-70, before the disease had appeared generally upon the coffee plantations, Ceylon exported 1,009,206 cwts. of coffee, consisting of 860,707 cwts. plantation coffee, and 148,499 cwts. native coffee. In 1876-77, when there were 52,000 more acres in bearing, the total exports were only 797,763 cwts., viz., 727,420 cwts. plantation coffee, and 80,343 cwts. native coffee.[1]

The yield of native coffee[2] has been steadily declining since 1868, owing to the want of high cultivation and manuring which have, in some measure, at least, saved the plantation coffee from being subject to the full influences of the disease. The culmination of crop and total value for native coffee was reached in 1868, the year before the leaf disease appeared, when 218,584 cwt. were exported. In 1877 the export of native coffee had fallen to 76,182 cwts., only a little over a third of what it was in 1868.[3] The influence of the disease has also seriously reduced the yield per acre. The Rev. R. Abbay, in the paper mentioned above, states that "Previous to and including 1871 the average yield for five years over the whole island had been 4·5 cwt. per acre, whilst for the five succeeding years the average has only been 2·9 cwt. a decrease in the production of somewhat more than one-third."[4]

The deficiency in value of crop has been variously estimated; "the average annual deficiency in the whole island has been estimated by some as at least 2,000,000*l*. Since the 'disease' made its appearance in 1869, the coffee enterprise has suffered to the extent of from 12,000,000*l*. to 15,000,000*l*. in crops alone."[5] A portion of the loss which the coffee estates have suffered may be and is, no doubt, due to exceptionally unfavourable seasons for the blossoming and development of fruit, and to the fact that many unsuitable areas were planted with coffee, which have since become unproductive; but there is a marked difference in the uniform succession of crops and in the yield per acre since 1871, even in the best coffee districts, which is evidently attributable to the action of the coffee-leaf disease.

When the trees are severely attacked by "disease," there is a premature fall of leaf and a check to the growth, which invariably results in a partial loss of crop. The trees also appear much thinner than formerly, having a wiry, sickly look, and do not make new wood so rapidly. As the disease shows itself mostly in dry weather, and just before the crop is ripening, its effect upon the trees is more severe and lasting than it otherwise would be; the tips of the branches often die back, involving, as the tree does not ripen all the berries, a great percentage of light coffee and black-hearted beans. The vitality of the trees being thus yearly weakened, there is often a failure of blossom even in what may be called favourable seasons, for though the blossom is forced out, it finds insufficient food-supply to support it, and, consequently, a large and wonderful show of blossom often ends in a total or partial failure of crop.

It appears that during the earlier years of its ravages the disease, after a very severe attack, would so completely disappear, and the trees, relieved from its enfeebling effects, would put forth such an abundant supply of new wood and foliage that it was confidently hoped that it was only a passing visitation, and that it would soon and entirely pass away. Even now its attacks are often confined for some time to certain districts, and even to certain parts of estates, but it seems to be seldom absent from patches of old and ill-cultivated coffee, and from native gardens. It soon, however, became evident, in spite of its fugitive character, that though the disease did not completely kill any trees, its accumulative effects upon them, and especially on the older trees, were such that they could not be depended upon to ripen their crop or to produce, except in alternating periods, a moderately average crop. In 1874 Dr. Thwaites reported that "there is great reason to believe, from what has been observed, that high cultivation, with judicious manuring, enables the tree to better sustain the attacks of the fungus, and to retain strength and vigour enough to produce a fair yield of berry." Encouraged by this opinion, planters adopted manuring operations generally, not as a cure for leaf disease, but in order to strengthen the trees and enable them the better to bear the double strain induced by crop and leaf disease. Though to some extent successful, it was noticed that, with the leaf disease present, the effects of manuring were not nearly so lasting as formerly, and were seldom apparent after the first or second year. There was also a less ready response on the part of the trees, and cases were not infrequent where trees had almost died out when forced to produce heavy crops, and others, where trees in a large degree had ceased to yield to any stimulus whatever.

3. *Remedial Measures*.—From what has been already mentioned it may naturally be supposed that the coffee-leaf disease and its effect on coffee cultivation in the East have occupied considerable attention during the last ten years, and, indeed, it may be looked upon as the most pressing and momentous of all questions affecting the prosperity and welfare of Ceylon, which depends so largely upon its coffee enterprise. Many suggestions have been made from time to time with regard to the application of suitable and effective remedies. As early as 1869 the Rev. M. J. Berkeley recommended the use of flowers of sulphur, or "one of the sulphurous solutions recommended for the extirpation of the hop-mildew," but the fugitive and deceptive nature of the disease and the vast area (over 200,000 acres) to be treated prevented any decided steps being then taken.

The hopes that were entertained respecting the temporary nature of the visitation and its possible mitigation by the application of suitable manures also led planters to look to indirect rather than direct means for checking the ravages of the disease. A few experiments were initiated, but from an imperfect knowledge of the disease and want of suitable apparatus no satisfactory results were obtained.

In January of this year a series of systematic experiments were initiated at Wallaha Estate, Lindula, in conjunction with the Hon. G. A. Talbot. In these experiments advantage was taken of the fact that the disease in its first or filamentous stage appears to exist as an *external* parasite upon the leaves and branches. It was found experimentally that an application of flowers of sulphur and coral lime entirely destroyed these external mycelial threads and without inflicting the slightest injury even to the most delicate parts of the plant.

This fact fully established, and being confirmed by subsequent experiments on larger areas, gave an entirely new aspect to the subject, and the present year has been signalised by an earnest and it is to be hoped a successful attempt to reduce the ravages of the coffee-leaf disease.

As sulphur had been used so extensively and so successfully against fungoid parasites in other parts of the world it may appear a matter of surprise that no steps had been taken long before this to test its efficacy on the coffee plant. In order to treat this disease successfully, however, it appears to be indispensable to carefully watch its various stages and apply specifics only when the disease is mostly external. During several months of the year, especially during a continuance of wet weather, the *vegetative* system of the *Hemileia* seems mostly to be developed, and as the mycelial threads are present *externally* upon the branches and leaves, it offers a favourable means for being treated.

Unfortunately the disease during this stage is entirely

[1] "Ferguson's Directory of Ceylon," 1876-78 Introd.
[2] Unpruned coffee grows with little or no cultivation in Sinhalese gardens.
[3] The falling off in native coffee is possibly not quite so much as these figures would indicate, for latterly an increasing quantity of native garden parchment is shipped as plantation coffee.
[4] Linnean Society's *Journal* "Botany," vol. xvii. pp. 173-5. [5] *Ibid.*

microscopical, and it requires very close observation even with the microscope to detect it. It is no wonder, therefore, that planters found it most difficult to decide when and how to apply remedies, and these considerations, together with others incidental to coffee cultivation, rendered a successful treatment, without scientific aid, both difficult and laborious.

When the results of the first experiments at Wallaba were published, the importance of the subject led the Colonial Government to take up further investigations, and to render special scientific aid to the planters in conducting their experiments. Experiments were organised on a large scale, and carried on in various districts throughout the island.

Meetings were also held, in which the development of the disease, and the results of more extended experiments and observations were given in detail.

As a result of this combined activity, a series of reports has lately been presented to the Legislative Council of Ceylon, embodying the results of the "Leaf-disease Inquiry;" these are published in the Sessional papers of this year. The results of the investigations, so far, are briefly summed up as follows:—

1. That the coffee-leaf disease is an organised fungoid growth, present on the estates in some form or other all the year round.

2. That in December and the early part of the year it is generally present as an external parasite upon the coffee trees, in the form of long filamentous threads which cover every part of the bark and leaves.

3. That while an external parasite and in the filamentous stage it is possible to destroy it most effectually, and by so doing to save the trees from the attacks of the fungus for at least one year.

4. That a mixture of sulphur and lime dusted by hand into the tree in the proportions of one of sulphur to two of lime has been found by experiment to be the most effective and suitable remedy which can be applied.

5. That the cost of the materials, at present prices *in Colombo*, together with the cost of application, will not exceed at the rate of R16·50 per acre.

6. That the application of sulphur and lime in the proportions recommended, by releasing the trees from a heavy drain upon their resources and restoring them to their natural condition, will be attended by a much more profitable result than any expenditure upon artificial manures.

7. That in order to assist the means used for checking the leaf disease it is most important that planters unite in the application of remedies and that they remove at once all sickly trees on their estates and those not likely to be crop producers, and prevent by every means in their power the re-infection of good coffee.

8. That in order to secure *perfect* freedom from leaf-disease it will no doubt be necessary to uproot all coffee trees on abandoned estates and old native gardens, and to take steps to prevent the disease from finding an asylum upon any plants not under careful cultivation.[1]

Judging by these results, which have been obtained by the united action of practical men of considerable knowledge and experience in coffee cultivation, aided by careful scientific observation, there is little doubt that the leaf disease can now be very effectually and conveniently treated, and if not completely exterminated, at least so materially reduced that it will not seriously injure the crops.

In the reports just quoted, great prominence is given to the necessity which exists for removing all old and sickly trees and up-rooting coffee plants growing without care or cultivation on abandoned estates and native gardens. Such trees appear to be the worst sufferers from leaf disease, and while they remain, are a continual source of danger to well-cultivated estates. One severely diseased tree is said to be sufficient to infect all trees in its immediate neighbourhood, and on that account a strong conviction is expressed in the Reports that little good can be expected from remedial measures of any kind, unless great care is taken to prevent the disease finding an asylum on "shuck" and abandoned coffee. The earnestness and intelligence which have characterised the action of the planters during the recent experiments lead to the hope that every means will be taken to check the development of the disease, and to increase the action of suitable remedies. The Reports also recommend the extended cultivation of other plants, such as tea and cinchona, in order to break the continuity of the coffee estates and restrict the action of the disease as much as possible.

On thus reviewing the present condition of coffee cultivation in Ceylon, there is much that is hopeful and satisfactory. Dr. Thwaites in his Report dated March, 1877, remarks that "Notwithstanding the continued prevalence of *Hemileia vastatrix* upon the coffee plants throughout the island, there would appear to be little, if any, diminution in the anxiety to invest in the cultivation of coffee; the high prices obtained, and the beneficial effects of judicious manuring, are giving so much confidence to planters." This feeling appears still to be maintained, for keen competition and high prices characterise all recent sales of suitable forest land. And while this shows that coffee cultivation still possesses the confidence of investors in new districts, many estates even in the oldest districts, are sold at prices which show they possess great vitality, and that where careful and intelligent cultivation is pursued they still offer a promising and attractive investment. It is gratifying to find that the planters are now quite conscious of the true nature of the disease, and thoroughly aroused to the necessity which exists for treating it on the lines which have proved so eminently successful for the last twenty years with the fungoid pests of the hop and vine.

By the extended cultivation of cinchona, tea, and other products, some of the conditions which have induced, or, at least, encouraged the ravages of the leaf-disease, will doubtless be removed, and in the renewed care and intelligence which are becoming daily more apparent in the methods of cultivation and the application of suitable manures, there is every reason to believe that coffee cultivation in Ceylon will be carried on under much more advantageous circumstances than at present, and while much that is now under coffee will probably be planted with tea and cinchona, the remaining lands will receive that due care and attention which cannot fail in time to restore the coffee estates of Ceylon to the position they have long held as one of the most successful and important of the enterprises of the East.

D. MORRIS

Kew, September 3

[1] Morris's Reports on "Coffee-Leaf Disease," Sessional Papers, Legislative Council of Ceylon, 1879.

OUR ASTRONOMICAL COLUMN

THE SATELLITES OF MARS.—In the Introduction to his Tables of the satellites of Uranus, Prof. Newcomb points out the advantage that might be derived, in systematic observations of the satellites by the preparation of a table showing the angles of position and distances corresponding to every 10° in u or the longitude of the satellite in its orbit, counted from the point in which it crosses the plane parallel to the earth's equator. From such a table the approximate positions of the satellites would be obtainable at any one opposition, with no further calculation than is required to determine the value of u for the time of observation. The more rapid geocentric motion of the planet Mars does not of course allow of this principle of computation being applied so as to attain the same degree of approximation as in the case of Uranus, but even with Mars it is likely that such a table, prepared with the values of the various auxiliary quantities for the date of opposition November 12, may facilitate observations, and we accordingly present one below:—

Argument u.		Position.		Distance.	
A.	B.	A.	B.	*Deimos.*	*Phobos.*
°	°	°	°	″	″
0	180	178·8	358·8	20·4	8·2
10	190	144·5	324·5	16·8	6·7
20	200	109·3	289·3	19·9	8·0
30	210	88·4	268·4	27·3	10·9
40	220	77·0	257·0	35·8	14·3
50	230	70·1	250·1	44·2	17·7
60	240	65·3	245·3	51·6	20·7
70	250	61·4	241·4	57·7	23·1
80	260	58·4	238·4	62·3	25·0
90	270	55·6	235·6	65·2	26·1
100	280	53·1	233·1	66·2	26·5
110	290	50·5	230·5	65·1	26·2
120	300	47·8	227·8	62·6	25·1
130	310	44·8	224·8	58·0	23·3
140	320	41·1	221·1	52·1	20·9
150	330	36·4	216·4	44·8	17·9
160	340	29·6	209·6	36·5	14·6
170	350	18·7	198·7	27·9	10·6
180	360	358·8	178·8	20·4	8·2

According to Prof. Newcomb's elements the values of the argument u at Greenwich mean midnight are—

Nov. 2 ...	... *Deimos* 331°·1	*Phobos*	89°·8
12 ...	... ,, 302·7	,,	217·7
22 ...	... ,, 274·4	,,	345·7

and the diurnal motions of u are 285°·1645 and 1128°·794 for *Deimos* and *Phobos* respectively, giving hourly motions of 11°·882 and 47°·033, whence u for the time of observation may be found. Or if the observer possesses Newcomb's memoir on the satellites he may find it from the table at p. 42. Then with u as the argument the above table gives roughly the angle of position and distance of the satellite, remarking that the former is to be taken in column A or column B, according as the argument is found under A or B. Thus for midnight on November 5 the value of u for *Deimos* is 106°·6, and for *Phobos* 236°·3, whence the positions and distances are: for *Deimos* 51° and 65″, and for *Phobos* 247° and 20″.

THE SATURNIAN SATELLITE, MIMAS.—This faint object was observed by Mr. A. Ainslie Common, of Ealing, with his 3-feet reflector, on the night of September 21, when close up to its conjunction with the following extremity of the ring, which was estimated to take place about 11h. 50m. G.M.T. With the elements which have been previously used in this column the satellite would be up to the ring at 11h. 53m. Such observations as this are of course much more valuable for the correction of elements than estimations of the times of greatest elongations; nevertheless as it is in or near the latter positions that the satellite is most likely to be visible in telescopes of inferior power, we subjoin the times of greatest elongations observable in this country up to the end of the present month:—

EAST.	h. m.	WEST.	h. m.
Oct. 9 ...	12 20	Oct. 16 ...	13 56
10 ...	10 56	17 ...	12 33
11 ...	9 53	18 ...	11 10
12 ...	8 10	19 ...	9 47
13 ...	6 47	20 ...	8 23
		21 ...	7 0
24 ...	14 10	Nov. 2 ...	12 58
25 ...	12 47		
26 ...	11 24		
27 ...	10 0		
28 ...	8 37		
29 ...	7 14		

THE MINOR PLANETS.—Two small planets assumed to be new have been detected by Prof. Peters, of Clinton, N.Y., apparently on September 22 and 26 respectively; the number being thus raised to 203. Prof. Watson, now in direction of the Washburn Observatory, Madison, Wisconsin, has selected the following names for planets discovered by him in 1877: for 174, *Phædra*; for 175, *Andromache*; and for 179, *Clytemnestra*. *Fortuna* will be in opposition on October 23 close up to perihelion, so that the possible brightness, 8·5m., will be at its maximum.

GEOGRAPHICAL NOTES

DR. HOLUB, the eminent African traveller, who is now in England on his way to his native country (Bohemia), intends, it is stated, shortly to undertake another exploring expedition. His return to Europe has for its main object the collection of the necessary funds for the new undertaking. He has formed plans for the formation of an international expedition, which is to be placed under his direction and which is to travel through Africa from Port Elizabeth towards Egypt. The exploring party is to consist of twelve members representing twelve different nations, and the costs of the expedition are to be defrayed by the different governments. The special purpose of the expedition is stated to be the opening of Central Africa towards the south and east and to facilitate the colonisation of the district between the Vaal River and the Zambesi. A correspondent in the *Times* gives the following interesting summary of the remarkable work accomplished by Dr. Holub:—"For seven years Dr. Holub has been exploring the country north and south of the Zambesi, alternating his exploring expeditions with months spent at the Diamond-fields, practising as a medical man to raise the requisite funds for his next journey. In this time the doctor has studied the habits of the Matabele, the Marutsi, Hottentots, Bechuanas, and numerous other tribes, living among them as their guest, and gaining their confidence by curing their sick. In Dr. Holub's third and last journey he has accurately surveyed the country from the Diamond Fields to the Zambesi, and the Zambesi from its junction with the Chobe to the Barotse country. His map of the Zambesi is on a large scale, and shows every island, creek, and rapid. To show the difficulties of this survey, it may be mentioned that, owing to the loss of his *Nautical Almanac*, his sextant was useless, and the bearings had to be taken by compass observations every 300 yards, while the distances, amounting in the various surveys to over 2,000 miles, were determined by *stepping*. That is, the explorer counted every step he took during a twenty-one months' walk. He arrived at Muchela Amsinga tired and unwell, but still full of pluck, and hoping to cross the continent and emerge at Loanda. Then fever came on, and his best canoe, containing all his gunpowder, and, worse than all, his quinine, sank in a rapid. He still pushed on, but at the Nambwe cataract he succumbed, and was carried back insensible by his native servants to lie ill during a period of sixteen months. Even during his illness, however, he was not idle, for being carried about in a litter and directing his men what to pick up, he made magnificent collections of plants and insects, with others of birds, weapons, native drawings, &c. The collection of beetles alone contains no less than 13,000 specimens. Dr. Holub is publishing the account of his journeys in Bohemian, English, German, and French, and is about to read a paper before the Geographical Society of Vienna. He will also read one before the Royal Geographical Society of London when he returns to England at Christmas."

DR. OTTO FINSCH, of Bremen, who is on a tour to Micronesia, by order of the Humboldt Institution of Berlin, arrived at Honolulu on June 17, and first of all proceeded to the island of Maui, where he spent some time in making scientific collections and observations of the Haleakala, the largest volcanic crater on the globe. After his return from Maui he made an excursion to the Bay of Waimanolo in order to visit the ancient Hawaiian

burial-grounds. The traveller has collected some 3,000 zoological and 300 botanical specimens, besides a splendid series of Kanaki skulls; all these collections were packed ready for conveyance to Berlin when he sent the news. On July 27 he left Honolulu for Jaluit (Bonham) in the Marshall group, and has no doubt by this time reached the very district he is specially to investigate. From Jaluit he will proceed to other islands in the neighbourhood.

FROM an early sheet of *Petermann's Mittheilungen* we learn that the Dutch exploring vessel *Willem Barents* arrived at Hammerfest on September 24, having succeeded in reaching Franz Josef Land. The expedition encountered stormy weather in September, and found much ice in the Kara Sea and to the north of Novaya Zemlya. M'Clintock Island, in the south of Franz Josef Land, was surrounded by ice, and on the return journey ice was found east of the 55th degree. They left the *Isbjörn* in Matotschkin Scharr. This *Isbjörn* is the little Norwegian cutter in which Capt. Albert Markham and Sir Henry Gore Booth have been cruising in the Novaya Zemlya seas, and which reached Tromsö on September 22. On June 4 they met with the first ice forty miles from the west coast of Novaya Zemlya, and finding Matotschkin Scharr impassable, they sailed along the west coast of Novaya Zemlya to Cape Nassau, when the *Isbjörn* was stopped by ice. Returning again, the Matotschkin Scharr was passed, but the Kara Sea was full of masses of ice. On their return they fell in with the *Willem Barents*, and Markham decided to press northwards again, and this time succeeded in reaching, on September 6, Cape Mauritius, the north point of the island. Pressing still further northward between Novaya Zemlya and Spitzbergen, the *Isbjörn* reached 78° 24′ N. lat., only about eighty miles from Franz Josef Land.

ADVICES received from St. Lawrence Bay state that the American Polar exploring vessel *Jeannette* arrived there on August 25, and sailed for Cape Serdze Kamen after taking in coal. It is believed that there is a prospect of an open winter in the Arctic Sea this year.

IN his last official report from Copenhagen, Her Majesty's Consul states that the Danish war vessel *Fylla*, which during the fishing season is stationed off the coast of Iceland, has made some deep-sea soundings and measurements, and brought home many interesting particulars respecting the currents and temperature of the Polar Sea. On one of these expeditions she penetrated so far north in the ice as to find cold water (*i.e.*, under freezing point) from two fathoms below the surface to the bottom, by which was proved the presence of an ice-cold polar current; the existence of this had not been previously ascertained, owing to the impenetrable ice-masses. The soundings were taken both on the north coast and in Denmark Sound. The extent of the polar ice is varying and changeable, for at the time the *Fylla* was able to penetrate many miles direct north in open water from North Cape, Iceland, a mail steamer could not enter Ofjord owing to the ice, and a French war steamer was stopped by ice about five miles from the coast between these points. During the whole time the *Fylla* met with very much drift-wood, which increased in quantity as she advanced northwards. The foregoing notes are of considerable interest when considered in connection with portions of Mr. G. F. Rodwell's letter from Iceland, in last number.

THE October number of the Geographical Society's monthly periodical opens with a long paper by Capt. G. Martin, on the information obtained in regard to the Kurram Valley during the survey operations of the Afghan expedition. At the present juncture, this paper will, no doubt, be read with much interest, but, though the author states that "he has endeavoured to be as brief as possible," we incline to the opinion that his observations might with advantage have been very considerably curtailed. In the geographical notes we find news respecting the Rev. T. J. Comber's expedition to the Congo, Danish discovery on the coast of Greenland, and the Dutch Arctic expedition. Some further particulars in regard to Mr. Keith Johnston's sad death and the East African expedition are also included under this head.

THE Marine Survey Department, Calcutta, has lately issued a hydrographic notice which contains some information in regard to Pemba Island and the adjacent coast of East Africa. The island is thirty-eight miles long and about thirteen miles wide, including the islands on its western side, which protect the numerous harbours there. The east coast is rocky and straight, with only a few slight indentations. The height of Pemba Island does not exceed 300 feet, and the surface is broken into ridges and valleys, covered with luxuriant vegetation. The soil is rich, the chief produce being cloves, most of the groves of which are situated on the west side of the island. All tropical cereals and edible roots flourish, and on the eastern side the Wapembe, or descendants of the aborigines, keep large herds of cattle. Cocoa-nuts abounded, but no oil-making is carried on, most of the nuts being consumed locally and the remainder sent to Zanzibar to be converted into oil. The greater part of Pemba Island is under cultivation, or is grazing-land, but a little forest exists here and there. The island is governed by a Wali, appointed by the Sultan of Zanzibar, and residing at Chaki Chaki, the only place of any importance.

NOTES

WE learn that Dr. Thwaites, F.R.S., C.M.G., has resigned the directorship of the Royal Botanic Gardens, Peradeniya, Ceylon, to which he was appointed in 1849. This step has been for some time contemplated by Dr. Thwaites, on whose somewhat feeble health the charge of the botanical interests of the island, especially in relation to the coffee-leaf disease and the introduction of new kinds of cultivation, has of late pressed heavily.

IN a recent paper to *La Nature* on the employment of the hydro-electric batteries and Reynier lamps for domestic lighting, M. Reynier comes to the following conclusions:—The most powerful battery is the Bunsen, Ruhmkorff model; but it is inconvenient and deleterious, and expensive. The most economical and constant battery is the Thomson; but it is costly and cumbrous. The most convenient battery would be a well-arranged rotatory one; but the price would be high (200 fr. at least) and the daily cost enormous. A battery as powerful as the Bunsen, as economical as the Thomson, and as convenient as a well-arranged rotatory one, would still be far from suitable for electric lighting. Hence it is not at present among hydro-electric batteries that we have to look for the solution of a domestic motor applicable to the present electric lamps.

AS will be seen from our advertising columns, the Council of the Entomological Society of London is authorised by Lord Walsingham and other gentlemen interested in the diseases of our native game birds to offer to public competition the following prizes:—50*l.* for the best and most complete life-history of *Sclerostoma syngamus*, Dies., supposed to produce the so-called "gapes" in poultry, game, and other birds; 50*l.* for the best and most complete life-history of *Strongilus pergracilis*, Cob., supposed to cause the grouse disease. No life-history will be considered satisfactory unless the different stages of development are observed and recorded. The competition is open to naturalists of all nationalities, and the same observer may compete for both prizes. Essays in English, French, or German, to be sent in on or before October 15, 1882, addressed to the

Secretary of the Society, 11, Chandos Street, Cavendish Square, W.

THE death is announced of Prof. Mohr, of Bonn University, at the age of seventy-two. Mohr, like his father, was originally an apothecary at Coblenz. In 1864 he was attached to Bonn University, and some of his works on chemistry, geology, and physics have been translated into foreign languages. His activity was inexhaustible.

AN experiment was tried on October 4 by M. Menier, in a large park belonging to him at Noyelles, on the banks of the Marne, about 50 kilometres from Paris, on the Eastern Railway. A part of the water power which he uses for his workshop operates on eight ordinary Gramme machines producing the current for the Serrin regulators or Jablochkoff candles. The current of two of these machines was sent into the park at a distance of 700 metres, where two others had been arranged on a truck and connected with a plough by a dragging rope. A number of furrows were then traced with this simple apparatus, and have been found equal to the work of four oxen. The experiment has been found so successful that M. Menier intends devoting a water-power of thirty horses to agricultural work round his workshop. He intends using water-pipes for placing his insulated copper wires, and expects to conduct his power to 5 kilometres from his mill in every direction, so to perform various agricultural operations on a surface of more than ten square miles.

THREE different telephonic companies are competing in Paris, viz., the Gower (magnetical), Bell, and Edison, the two latter working with the microphone. It is said that the Bell and Edison Companies will enter into a working arrangement, or a fusion.

THE city of Lille, in French Flanders, sends every year to England the best English scholars of the Municipal School. This year the journey made at the expense of the city has taken unprecedented extension. The number of travelling pupils was twenty-three, and the excursion occupied a fortnight, during which not only London, but Edinburgh, Dundee, Glasgow, Newcastle, Durham, and York were visited.

THE tramway from Naples Observatory to the foot of the cone of Mount Vesuvius is nearly completed, and will be opened early next year. A steam-engine at the summit will draw the trams up by a windlass on Spielg's system.

WE understand that by the retirement of Dr. Gilchrist from the charge of the Crichton Asylum at Dumfries, a very important and valuable appointment is now open to the psychological branch of the medical profession.

A FACULTY of Medicine has been created at Bordeaux. M. Ferry, the Minister of Public Instruction, will be present at the ceremony of laying the first stone.

THE French Minister of War has published a regulation for organising optical telegraphy in time of peace. The several places on the French frontier are to be connected by posts; apparatus are to be manœuvred by persons trained and keeping records of communications sent or received. This new service is to be placed nnder the supervision of the Director of Aërial Communications, who already has command of the balloonists and the colombophiles for carrier-pigeons.

THE *Times* Geneva correspondent states that a fisherman has found a very remarkable weapon near the lake-dwelling of Locras, in the Lake of Brienz. It is a double battle-axe of pure copper, forty-two centimetres long, and weighing three kilogrammes. Massive and heavy in the middle, it broadens out gradually into two cutting edges, each having a width of twelve centimetres. It has been added to the collection of Dr. Gross, at Neuveville. Several similar weapons have been found in Denmark; but, so far as is known, this is the first of the kind discovered in Switzerland. The lake-dwelling of Locras is assigned by archæologists to the age of stone.

AT Trier (Treves) a fresh discovery of colossal remains of Roman structures has recently been made. They consist mainly of a large wall, 1·88 metres thick, with two other ones running parallel to it and only 90 centimetres apart. Between the latter two, at a depth of 8 metres below the present surface of the ground, there is a vaulted canal, and a little further on an enormous cellar vault. The foundations of the two parallel walls have in some parts not been reached at a depth of 9 metres. Archæologists are at present at a loss to know what may originally have been the nature of the structure, as nothing at all resembling it has ever been discovered.

WE have received from the Dundee Naturalists' Society very satisfactory reports of the work done during the sessions 1877–8–9.

IN a recent communication to the Vienna Academy, on the cause of excitation of electricity in contact of heterogenous metals, Prof. Exner offers proof that the electromotive force is always in direct relation to the heat of combustion of the metals in question, provided they are in air. Such proof is quantitatively furnished for the combinations of Zn, Cu, Fe, and Ag, with Pt. Further it is shown that the so-called contact-force of two metals changes, whenever these are no longer in air, but in some gas acting in a different way on them chemically. Numerical proof of this is given in the case of Ag, according as this metal is in air or in an atmosphere of chlorine. Since the numerical values obtained in this research, for the contact-force, as also the few older determinations are in full harmony with the chemical theory of this mode of electric excitation, and the experiments are contrary to the voltaic theory, the author considers further adherence to the latter impossible.

THE radicles of seeds lying on the surface of the ground penetrate into the ground only under certain conditions. According to recent observations by Dr. Richter, of Vienna, these are of the following nature:—1. The penetration takes place only when the temperature exceeds a certain minimum above the lower zero of germination, depending on the species of the plant. 2. This minimum is much lower, for one and the same plant species, if the seedling is exposed to light, than if it is kept in darkness, the reason being that in the former case a transformation of light into heat occurs (as shown by experiments of cultivation at temperatures above the optimum of germinating temperature of particular plants). 3. A pressure of the roots on the ground, whether through formation of root-hairs, or from external causes, favours the penetration of the roots. 4. The nature of the ground affects the penetration of roots, only in that the latter occurs more easily the less resistance the ground presents to the roots. 5. Geotropism is naturally concerned most largely in the penetration of the roots. The light affects it in so far as by production of heat, it favours the growth generally, and therewith the geotropic downward-bending. On the other hand, negative heliotropism is (contrary to expectation) not concerned in penetration of illuminted roots into the ground.

THE Rouen journals report an invasion of swarms of bees in several houses of the town. In a confectioner's establishment legions of these bees took possession, making it impossible for the workmen to continue their occupations. Nearly every inmate of the place was stung, and one person was maltreated so severely that medical aid had to be called in. An attempt was made to get rid of these importunate guests by burning sulphur to asphyxiate them, but the bees took refuge in the upper storeys

and when the smoke had abated, they descended again, and were as troublesome as before.

THE general meeting of German Archæologists and Historians took place at Landshut (Bavaria) on September 14 last, and was well attended by members from all parts of Germany. Prof. Ohlenschlager, of Munich, delivered the first lecture "On the Survey made of the so-called Devil's Wall in Bavaria." Great interest was evinced in a paper read by Prof. Rhiza, of Vienna, "On the Marks made by Masons and Stone Workers at different Periods and in Different Districts."

KARL VON SCHERZER, Austrian Consul-General at Leipzig, has been nominated honorary member of the Senkenberg Natural History Society at Frankfort-on-the-Main.

THE "Oberlausitzische" Scientific Society at Görlitz (Silesia) celebrated the centenary of its foundation on October 8. At the same time the 153rd General Meeting of the Society took place.

AT the Baden-Baden meeting of the International Society for the Prevention of the Pollution of Rivers, the Soil, and the Atmosphere, which took place on September 16 last, the three principal addresses were by Professors Reclam, of Leipzig, Vogt, of Berne, and Ewich, of Cologne. Prof. Reclam spoke on canalisation and the pollution of rivers in Germany and England; Dr. Vogt on the influence of the sun upon the walls of houses; and Dr. Ewich on the origin of springs and wells.

IT may interest our readers to know the elevations which at present are reached by lines of railway in different parts of the world. The Apennine Railway reaches its highest point at an elevation of 617 metres above sea-level; the Black Forest Railway ascends to 850 metres, the Semmering line to 890, the Caucasus line to 975 metres. The St. Gothard tunnel is 1,154 metres above sea-level; the railway across the Brenner reaches 1,367 metres; the Mont Cenis Railway ascends to 1,338 metres, the North-Pacific line to 1,652, the Central-Pacific to 2,140, and the Union-Pacific to 2,513 metres. The highest of all is the line across the Andes, which reaches an elevation of 4,769 metres.

DR. BRAUNS, of Halle, has been appointed Professor of Mineralogy and Palæontology at the Japanese University of Tokio. It is stated that some twenty-five amongst the teachers at this University are Germans.

AT Carlsruhe a meeting of a large number of agricultural chemists from all parts of Europe took place on September 16 and 17 last.

WE have a satisfactory report of the Queenwood Mutual Improvement Society for the end of the summer term 1879. A good deal of practical natural history work seems to be done by the members, and the report contains an interesting account of three carrion crows that were tamed by some of the boys, remaining about the premises, "showing themselves as familiar and companionable as the most faithful dogs."

ON Thursday last the Chester Society of Natural Science held a very successful *conversazione*. The Kingsley Memorial Medal, established in memory of the Society's first president, was awarded to Sir P. de M. Grey Egerton, for "having contributed materially to the promotion and advancement of natural science," and the Kingsley Memorial Prize to Mr. G. Shrubsole, jun., for his collection of fossils illustrating the carboniferous limestone, millstone grit, and coal measures.

MR. F. H. BROOK, of Walworth, has sent us a useful Price List of Electrical Apparatus, containing upwards of 450 items.

THE annual exhibition of the Photographic Society was opened on Monday, at the Gallery, 5, Pall Mall, East.

WE very much regret to learn that the publishers of the *American Chemist* have been obliged to discontinue the publication of that valuable journal.

A DISCOVERY calculated to throw some light on prehistoric man has recently been made by the excavation on the banks of Lake Ladoga of a human skeleton belonging to the stone period, along with many well-preserved skulls and bones, remains of plants and animals, and instruments of stone and bone. These remains were found at a depth of from about 12 to 20 feet below the surface of the lake.

TWO shocks of an earthquake were felt at Annecy, Savoy, at 4 A.M. on Saturday, both accompanied by a rumbling noise.

MR. STANFORD has published a useful Section of British Strata, showing the order of superposition and maximum thickness of strata in the British Islands, by Mr. James B. Jordan. The section was originally prepared as an Index of Colours to Stanford's Geological Map of the British Islands, edited by Prof. A. C. Ramsay, by whom it has been revised and corrected.

THE Museum of the French Colonies at Paris, which, as we stated, has received a sensible augmentation by the addition of a large part of the Algerian collections, is undergoing a total reorganisation. A new director and sub-director have been appointed.

THE Peking correspondent of the *North China Herald* learn that the engagement of the geologist and mining expert, Mr. Arnold Hague, by Li Hungchang, has terminated, owing to the obstructions constantly put forward by the Central Government. A few metal-bearing localities have been examined, but noting definite has been learned of the resources of the province of Chihli. At the date of the letter referred to Mr. Hague was at Peking, on his way to Mongolia, where he intends to make some excursions, partly with a view to scientific investigations. He will afterwards return to the United States to take up an official appointment in connection with certain new systematic surveys which it has been determined to make there.

THE Government of Victoria have just appointed a board to advise them as to the best mode in which assistance can be given to further the development of the auriferous and mineral resources of the colony.

NO. 3 of "Dimmock's Special Bibliography" (Cambridge, U.S.) consists of a full list of the writings of Samuel Hubbard Scudder, which ought to be specially valuable to entomologists.

WE have on our table the following works:—"The Spiders of Dorset," Rev. O. Pickard Cambridge; "Chemical and Geological Essays," by T. Sterry Hunt (Trübner); "Deaths in Childbed," Dr. Æneas Munro (Smith, Elder, and Co.); "The Silk Goods of America," W. C. Wyckoff; "Structural Botany," Dr. Asa Gray (Trübner); "Luxurious Bathing," A. W. Tuer (Field and Tuer); "Phrenology Vindicated," A. L. Vago (Simpkins); "On the Diffusion of Liquids," J. H. Long (H. Laupp); "Reform Essays on Incentive Religion and Warfare;" "Farming for Pleasure and Profit" (Poultry Keeping), Arthur Roland (Chapman and Hall); "Manual of Practical Anatomy," J. Cossar-Ewart (Smith, Elder, and Co.); "Rays from the Realms of Nature," Rev. James Neill (Cassell); "Jack's Education; or, How He Learnt Farming," Prof. Henry Tanner (Chapman and Hall); "Vocal Physiology and Hygiene," Gordon Holmes (Churchill); "Fauna der Gaskohle und der Kalksteine der Perm Formation Böhmens," Dr. Ant. Fritsch.

THE additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, presented by Sir Arthur Scott, Bart.; a White-

cheeked Capuchin (*Cebus lunatus*) from South America, presented by Mr. Adrian Hope, F.Z.S.; an American Red Fox (*Canis fulvus*), a Rough-legged Buzzard (*Archibuteo lagopus*) from Labrador, presented by Lord Hobart; three Vulturine Guinea Fowls (*Numida vulturina*), a Crested Guinea Fowl (*Numida cristata*) from East Africa, presented by Vice-Admiral John Corbett, C.B.; two Malabar Mynahs (*Sturnia malabarica*) from Hindostan, a Chinese Mynah (*Acridotheres cristatellus*) from China, a Waxwing (*Ampelis garrulus*), European, presented by Mr. A. F. Weiner, F.Z.S.; five Fat Dormice (*Myoxus glis*), European, presented by Mr. Edwin Liot; seven Green Tree Frogs (*Hyla arborea*), a Green Lizard (*Lacerta viridis*), three Spotted Salamanders (*Salamandra maculosa*), European, presented by the Rev. S. R. Wilkinson, F.Z.S.; an Anaconda (*Eunectes murinus*) from South America, presented by Capt. E. Ball; an Elliot's Guinea Fowl (*Numida ellioti*), a Vulturine Guinea Fowl (*Numida vulturina*), three Mitred Guinea Fowl (*Numida mitrata*) from East Africa, a Booted Eagle (*Nisaetus pennatus*), European, purchased.

ON THE GRADUAL CONVERSION OF THE BAND SPECTRUM OF NITROGEN INTO A LINE SPECTRUM

PROF. WÜLLNER, of Aachen, has recently published a treatise on the two different views which are held by physicists with regard to the various spectra presented by gases which are rendered incandescent by means of induction sparks. One of these views was first stated by Ångström, who thought that for a certain gas only one spectrum was possible, and that this spectrum consisted of lines only. All band spectra which occasionally appeared when gases were examined in the way mentioned, he ascribed to impurities. The band-spectrum of nitrogen, according to his idea, belonged to oxides of that element. He believed that as long as the current passed through the gas without giving a spark, the oxide was rendered incandescent as such, without decomposition, and that the spark decomposed the oxide, and that only then the nitrogen could give its own line-spectrum. Later on Ångström modified this view, and admitted that an elementary substance might give several spectra when rendered incandescent in the gaseous state, but he still held that in this case the element in question entered into isomeric compounds with itself, and that the different spectra belonged to different isomeric compounds. Mr. Lockyer afterwards defined this view more clearly, stating his opinion that the line-spectrum is produced by simple atoms, and the continuous or channelled-space spectra by conglomerations of molecules.

Prof. Wüllner, however, does not consider this hypothesis necessary for the explanation of the different spectra of elements, but holds that they may be explained by Kirchhoff's maxim. Prof. Zöllner has pointed out that the light emitted by a radiating layer of gas must essentially depend on the thickness and density of the layer. Prof. Wüllner, therefore, after having first confirmed the fact that the line-spectrum of elementary gases only appears with the real electric spark, the band-spectrum, however, when in the gas the electro-positive brush and glow appears, ascribes the different spectra to the differences in the radiating layers of gas. He believes that in the spark only the molecules struck by the spark are glowing, therefore almost only a linear row of molecules; thus in the spectrum only the absolute maxima of the emission power, which correspond to the temperature of the spark, become apparent. If, however, in the positive brush light the whole quantity of gas contained in the spectral tube is rendered incandescent, then it is always a relatively thick layer which emits light; in the spectrum all those kinds of light must show themselves for which at the respective temperature the power of emission is above zero. But since the incandescent gas is always of relatively small density, all the differences in the emission power of the various kinds of light must become apparent in the spectrum, and thus the latter must be richly varied or shaded; this is indeed the case in the band-spectra of gases. Prof. Wüllner adduces the spectra of iodine vapour as proofs of the correctness of his view. When rendered incandescent by means of a hydrogen flame, iodine vapour gives the negative absorption spectrum, which is of the same character as the band-spectra of gases; if rendered incandescent through the spark, the glowing iodine molecules give a bright line-spectrum.

The band-spectrum of nitrogen shows, that this element at the temperatures obtained by electric discharges possesses quite as great a power of absorption as that of iodine vapour at low temperatures, because the band-spectrum of nitrogen is essentially of the same character as that of iodine vapour, however different it may be from it in detail. Of all other gases, nitrogen must therefore be particularly adapted for showing, through the examination of the light it emits, the dependence of spectral phenomena from the thickness and density of the radiating layer of gas, and thus for furnishing the proof that there is no constant spectrum of nitrogen, but that a certain spectrum exists only at a certain temperature and density of the gas. This indeed is the question upon which turns the difference of opinions of Ångström and Lockyer on the one hand and of Wüllner and Zöllner on the other; the former ascribing the different spectra to chemical differences in the molecular conditions of the gas, the latter merely to differences of temperature, density, and thickness of the radiating layer.

In a former treatise on the nitrogen spectrum, Prof. Wüllner, without having recognised the importance of the density of the radiating layer with regard to the light emitted, pointed out that when the pressure in a nitrogen tube is diminished to such an extent that it ceases to be measurable, the brightness of the spectrum decreases, and in such a manner that the darker parts first fade away, so that at last only the brightest parts remain. He added that in this way the nitrogen spectrum in its character approaches a spectrum of the second order (the name given to line spectra by Plücker) without, however, changing to the nitrogen spectrum of the second order, since no new bright lines appear. At that time, however, Prof. Wüllner did not continue his researches in that direction, and in particular he did not examine whether the bright parts remaining do indeed correspond to the maxima of the complete band spectrum, because the spectra he obtained at those pressures were too weak to allow of measurements being made with the instruments then at his disposal. Lately, however, the Professor has minutely examined the nitrogen spectrum in this sense, employing a simple contrivance for rendering the spectra bright enough for measurements, even at the lowest pressures. This consisted in the employment of spectral tubes of very narrow calibre (about 2 mm. in diameter).

It must be remembered here that the temperature of the gas, which is caused by the induction current, rises with decreasing diameter of the tube. (If, however, the tubes were taken too narrow, the current at once broke them.)

Since the resistance in the tube rises as the density of the gas decreases, at least from a certain point of low pressure downwards, the temperature rises as well. If the rise in the temperature was sufficiently great, the experiment described by Prof. Wüllner necessarily decided the only hypothetical part in his conception of spectral phenomena, viz., whether with a rising temperature the absorption power for the various kinds of light grows in a similar manner or not. If it does grow simultaneously with the temperature, then the relative maxima of intensity of light which the complete band spectrum shows must always remain the same; the bright parts remaining at the lowest density must correspond to the maxima of the band-spectrum. If the contrary is the case, and this is what Prof. Wüllner assumes, then dark parts in the band-spectrum may become the brighter ones as the density decreases, and the bright parts remaining at the lowest pressure may be situated at places in the spectrum differing widely from the maxima of the band-spectrum. The first part of the experiment therefore consisted in an exact determination of the relative maxima in the band-spectrum of nitrogen for the sake of comparison. This is minutely described in Prof. Wüllner's paper. The final results of the observations were in complete accordance with the Professor's conception of the spectral phenomena. There is indeed no definite nitrogen spectrum when in layers of sufficient thinness the density of the gas is reduced below a certain limit. The band spectrum changes step by step into a line-spectrum; this, however, is not identical with the line-spectrum produced by the spark, but has only a certain number of lines in common with it. In this gradual change it is easy to follow the displacement of the maxima of brightness which takes place little by little as the temperature rises, and is quite conspicuous in several places; this displacement is the very cause why in this line-spectrum the lines in places differ widely in their situation from the maxima of brightness of the band spectrum.

Prof. Wüllner then gives an exact description of that part of

the complete band-spectrum (at a pressure of about 5–10 mm.) in which the variability of the spectrum is most conspicuous, viz., in the green and blue (from wave-lengths 562 to 449); this is followed by an account of the gradual changes taking place in two different places when the density of the gas is decreased. It would lead us too far to enter into the details here; suffice it to say that the richly-shaded band-spectrum changes quite gradually into a line-spectrum, and that most of the lines of the latter are in places which show no maximum of brightness in the band-spectrum. It results from these observations that the positions of the maxima of emission-power do not remain at all the same in all temperatures, but that in consequence of the changes of temperature accompanying the decrease of pressure they may be considerably displaced.

Prof. Wüllner gives the reasons why the wider tubes are unsuitable for the gradual conversion of band-spectrum into line-spectrum, and eventually describes the differences between the line-spectrum obtained from the band-spectrum in the manner described, and the line-spectrum obtained by the spark. Upon comparison of those regions in the two spectra which were examined more closely (beginning at wave-length 572), it was found that in the spark-spectrum there are about forty lines in this region. Of these eight correspond very closely to maxima or lines in the fully developed band-spectrum. The number of coincidences with the lines of the low density line spectrum is, however, much greater; perfect, or very nearly perfect coincidence occurs in nineteen lines, *i.e.*, about half the number, and amongst these there are four which are the same in the three different forms of the nitrogen spectrum. The brightest lines of both line-spectra are, indeed, perfectly coincident. These are the yellowish-green lines 568,4 and 567,1, the green lines 500·7 and 500·4 (which result from the green-channelling described in detail) and the blue line 463·2 (developed from the blue channelling). Another interesting similarity exists between the two line-spectra, however differently about half of their lines may be situated.

Plücker and Hittorf distinguish five principal groups in the line-spectrum of nitrogen, between which there are other single lines. Of these five groups Nos. II. to V. belong to the region specially studied by Prof. Wüllner. These groups are:—

Group II. between wave-lengths 577—567
Group III. „ „ 555—545

Between groups III. and IV. there are first three lines: 535·6, 534·4, and 532·3; and then two lines: 518·1, and 517·6.

Group IV. between wave-lengths 508—499

Between groups IV. and V. there are first four lines: from 489·6, to 484·8, and further on three lines: 480·5, 479·0, and 478·1.

Group V. between wave-lengths 464·5—460·2.

All these groups are situated in such parts of the spectrum where also the line-spectrum developed from the band-spectrum is very rich in lines. It follows, therefore, that the spark-line spectrum is developed, on the whole, in such places which show the greatest variability, even in a gradual decrease of the density of the gas, and which are richest in lines in the low-density line-spectrum.

Prof. Wüllner recapitulates his interesting treatise in the following manner:—The course of spectral phenomena of nitrogen, which takes place when the gas is gradually reduced in density in tubes of sufficiently small diameter, shows exactly those changes which may be deduced from Kirchhoff's maxim, that the smaller the number of incandescent molecules, the more the spectrum contracts into a number of bright lines.

At the same time it may be directly observed when the density of the gas is decreasing, how, in consequence of the temperature rising through increasing resistance in the tube, the maxima of brightness change their position, how the maxima of the fully-developed band-spectrum fade away, and how the lines become prominent in places which are either secondary or tertiary maxima or uniformly illuminated regions in channelled spaces. Now, if we further consider that the lines of the spark-spectrum, compared to those of the former line-spectrum, are not more considerably displaced than the latter are with regard to the maxima of the band-spectrum, then we can hardly doubt that in the different forms of the nitrogen-spectrum we see nothing else but the light emitted each time in accordance with the different temperature, density, and thickness of the radiating layer of gas, and that a new hypothesis for the explanation of these spectral phenomena is unnecessary and superfluous.

A HISTORICAL SKETCH OF THE VARIOUS VAPOUR-DENSITY METHODS[1]

ALTHOUGH Southern,[2] in 1803, made some very careful experiments to determine how much water was required to furnish 1 cubic foot of steam at various pressures, still the foundation of vapour-density methods was laid by Gay-Lussac.

He, in 1811,[3] started on the correct basis of accurate work when he heated a weighed quantity of substance over mercury in a graduated vessel. Muncke, in 1816,[4] heated the substances *in vacuo* in elliptic glass balloons of 155 c. i. capacity, closed with a stop-cock and with thermometer and syphon barometer suspended inside. In 1822[5] Cagniard de la Tour determined the combined effects of heat and pressure on certain volatile liquids, but as his results were on the question of maximum vapour-density, they hardly enter the domain of the present sketch. In the same year Despretz,[6] who gave no drawing, and only a very imperfect description of his apparatus, published a method in which he used a 9-litre exhausted globe, and made his determinations at atmospheric temperatures, employing only a small quantity of substance.

In 1826 Dumas,[7] wishing to operate on substances which attack mercury, worked out and published his well-known method in which the volume is definite, but the amount of substance required to fill that volume with vapour has to be subsequently determined.

In 1833[8] Mitscherlich proposed using tubes, sealed at one end and drawn to a neck at the other, instead of bulbs, and gave details and drawings of the apparatus for heating them; but Dumas, two years later, objected to the proposed alteration in his method, for he wrote:—

"We must then leave to this operation all its simplicity to make it essentially practical, and such, in fact, that with an ordinary cast-iron pot and some pieces of iron wire we can perform it. This is what I have done from the first, and what I persist in doing, my aim never having been to make a piece of apparatus for the cupboard of the physicist, but to give chemists a simple and eminently practical and yet exact process. After all *they* are the only ones to be considered."[9]

Deville and Troost,[10] however, in 1860, in referring to that same apparatus, called it "La méthode si élégante de M. Mitscherlich."

Bineau, in 1838,[11] published an elaborate paper, but unfortunately without any drawings, for when we read the following paragraph, "The bodies on which I have worked have been volatilised sometimes by the aid of heat by following the process of Dumas or that of Gay-Lussac, sometimes without elevation of temperature by working in the barometric vacuum or by allowing the vaporisation to take place in dry air or hydrogen," we cannot but feel that an enormous amount of valuable work has been lost for want of details. In 1844 we find Cahours,[12] as well as Bineau,[13] at work at the same subject. In 1846 the latter[14] repeated the experiments of Despretz with slight modifications, but called attention to the fact that the result was seriously affected by very small errors in reading off the mercurial column.

In 1849 Regnault[15] described an apparatus very similar to that of Mitscherlich, but arranged the tube supports so that the two could be withdrawn simultaneously; he also dispensed with sealing the tube containing air by providing it with a stop-cock. Bineau,[16] in 1859, in order to operate at high temperatures, coated the glass tubes with clay and heated them in a sand-bath.

Regnault,[17] in 1861, to obtain the same result, used iron tubes, and to ensure uniformity of temperature, heated them in a cast-iron tube which was made to revolve over gas-burners. The tube which served as air-thermometer was furnished with a stop-cock, but that containing the substance only terminated in a small aperture, and was not closed, as a snfficient quantity was

introduced before the heating, to allow it to be taken for granted that during the experiment there was no residual air.[1] Another method of Regnault's was to have two iron bottles of as nearly as possible the same size cast in one piece. In one of these the substance was placed, and in the other a small quantity of mercury. The necks were then partially closed by loose stoppers, and the system was heated in a muffle. After heating it was withdrawn and allowed to cool, and the quantities remaining in the bottles were determined by suitable means.

Grabowski,[2] in 1866, did much to shorten the Dumas calculation, while he allowed the method to retain all its accuracy and simplicity when he proposed to heat a bulb containing air in the same bath and of the same size as that containing the substance. After being heated the two bulbs were then sealed at the same temperature. Bunsen,[3] in 1867, employed an air-bath similar in principle to those of Mitscherlich and Regnault, but heated it by a very elaborate arrangement of gas-burners. He also simplified the calculation by taking care that *all* the tubes were of *exactly* the same weight and same size. He did not seal the tubes, but closed them by glass caps lined with india-rubber and fitted with glass plugs. Dumas,[4] in cases where the vapour rendered the outlet difficult to seal, used globes fitted with ground stoppers.

For the Dumas process at high temperatures Deville and Troost,[5] in 1857-9, recommended heating the bulb in a specially constructed furnace in the vapours of substances having high but definite boiling-points, such as mercury, sulphur, zinc, or cadmium (in 1873 Dewar and Dittmar[6] used a bath of boiling zinc in experiments on the vapour-density of potassium); for temperatures above the boiling-point of sulphur they used porcelain globes. For[7] temperatures up to that point the smaller and more compact apparatus devised by Greville Williams answers admirably.

Roscoe,[8] last year, in determining the vapour densities of the chloride of lead and thallium, used porcelain globes of 300 c.c. capacity, heated in a muffle, but determined the temperature by the method of specific heat, a large piece of platinum being employed for the purpose, and checked the result by the simultaneous determination of the vapour-density of mercury.

For[9] working at a reduced pressure Regnault proposed partially exhausting the bulb by means of an air-pump during the experiment; when the desired temperature was reached, it was sealed off at a point where the neck had been narrowed to a convenient size. In 1876 Habermann[10] gave a complete diagram of the apparatus, replacing the air-pump by a Bunsen-pump; but although he made no alteration in the method, still it was referred to by Sommaruga[11] as Habermann's.

The readiest method of determining the *residual* air is that of Greville Williams,[12] viz., to measure by means of a burette the quantity of mercury which is required to displace it. Deville and Troost[13] recommended weighing the mercury required.

Various experiments had been performed on vapours mixed with air, but the main point in Playfair and Wanklyn's[14] method (1861) consisted in stopping the supply of vapour before the bath in which the bulb was being heated had attained its maximum temperature.

Natanson,[15] in 1855, in order to use the Gay-Lussac method up to a temperature of 300°, heated the upper part of the tube by means of charcoal in a cylindrical furnace, and determined the temperature by thermometers suspended in the air-space between the graduated tube and the inner tube of the heating apparatus. In correcting for the tension of mercury-vapour he used Avogadro's tables.

Greville Williams[16] in 1857, wishing to make some determinations at varying pressures, devised the following method:—The graduated tube is, after it has been filled and the bulb has been inserted, screwed by means of a nipple cemented to the bottom into an orifice in the top of a small metallic cistern into a second orifice in which a long open glass tube is fitted. Into this tube mercury is poured until the required pressure is obtained. To reduce the pressure the excess of mercury is allowed to escape by a tap in the side of the cistern. The whole is heated in a water- or oil-bath.

In Regnault's[1] apparatus for the same purpose the two tubes are fastened to the bottom of the water-bath, and are connected by a T-piece, which is closed by a 3-way cock of special construction.

For determinations[2] up to 150° Greville Williams's compact modification consists in replacing the large vessel of mercury and the open glass cylinder by a cylinder closed and rounded at the lower extremity so as to resemble a large test-tube. This is then filled to a depth of 50–60 mm. with mercury, and above that with water or oil to a convenient height. The graduated tube is filled and the bulb inserted over the mercurial trough; it is then immersed in the large tube by means of a rod having at the end a small cup containing mercury. The large tube may be supported on wire gauze and heated by a Bunsen burner, or may be placed in a shallow oil-bath.

Schiffin,[3] in 1862, proposed steadying and manipulating the graduated tube by means of a loaded handle, which was secured to its upper extremity by spring clips.

Grabowski,[4] in 1866, replaced the charcoal furnace of Natanson by a very much neater air-bath heated by gas, but the chief merit in his method is that a tube containing air is heated by the side of that containing the substance. As soon as the substance is all converted into vapour, air is passed up into the second tube until it occupies as nearly as possible the same volume as the vapour. After the operation the air is measured at atmospheric pressure and temperature.

Croullebois,[5] in 1874, reverted to Bineau's method of using a large globe with a long tube, but took the precaution to heat the upper portion in a water-bath. Deville,[6] however, criticised his method rather severely, and pointed out that it was an unwieldy apparatus to manipulate.

In 1868, Hofmann,[7] in modifying the Gay-Lussac method, while he adopted the long tube which had been previously used by Bineau, Playfair, and Wanklyn, and Grabowski, introduced such an important alteration into the apparatus that it is not spoken of as his modification, but as his method. Instead of heating the substance-tube by a water-, oil-, or air-bath, he simply inclosed it in a slightly larger mantle tube, and passed the vapour of a liquid of definite boiling-point through the intervening space, selecting the liquid according to the temperature required. By this means he not only rendered the apparatus much more compact, but he maintained a steady temperature with the greatest ease. Wichelhaus,[8] in 1870, anxious to avoid the uncertainty introduced by the doubt as to the temperature of the column of mercury between the bottom of the outer tube, and the trough, dispensed with the latter by fixing to the lower extremity of the substance-tube an inverted syphon containing mercury. Then by lengthening and suitably enlarging the lower extremity of the outer tube, the whole of the inner one can be surrounded by vapour.

Grabowski,[9] in 1875, in order to obtain a high temperature, employed the vapour of naphthalene as the heating medium in using Hofmann's apparatus; but Engler,[10] in the following year, finding that the stoppage of the tubes from the solidification of the condensed hydrocarbon was troublesome, proposed to obviate the difficulty in the following manner:—He fixed to the lower end of the outer tube a metal socket provided with a short side-tube similar to those used for heating funnels. Then, by boiling the heating medium in this tube and allowing the vapour to cohobate in the space between the two glass tubes, he dispensed with all the arrangement of flask, tubes, and condenser.

Hofmann,[11] at the same time, made several modifications in his apparatus: 1. He proposed heating the whole length of the inner tube by making the outer one long enough to enter the mercury in the trough, and provided for the escape of the condensed liquid and excess of steam by having a small side-tube affixed a short distance above the level of the mercury. 2. Finding that graduated tubes were very liable to crack, he pro-

posed using plain ones in the following manner :—In the bottom of the mercurial trough he placed a piece of sheet india-rubber attached to an iron plate, and provided with a groove on its upper surface; the iron plate was furnished with a handle. During the heating the inner tube stood over the groove to allow of the escape of the mercury. When the level became stationary communication with the mercury in the trough was cut off by shifting the india-rubber disk until the inner tube rested on the flat surface. The height of the column in the inner tube was then noted by means of a cathetometer; the outer tube was then removed and a gummed label attached to the inner one to indicate the mercury level. After cooling, the volume of the vapour is determined from direct measurement. (3) In order to avoid the cracking of the tubes in cases where liquids of high boiling-point were used, he proposed connecting the lower end of the outer tube with the inner one by a cork through which two tubes leading to the flask or boiler passed. One of them led below the liquid, while the other, which was provided with a stop-cock, reached only just below the cork. If this stop-cock be closed while the liquid is being heated, a portion of it is forced up the space between the two glass tubes, and thus the mercurial column is heated more gradually. When the liquid reaches the boiling-point the stop-cock is opened, and the circulation of the steam proceeds as usual. The upper part of the outer tube must be sufficiently elongated or provided with a small tube leading to a condenser.

Brühl [1] proposed working the Hofmann method at a very low pressure by employing a tube 1·5 metres long, with only a small quantity of substance, and was therefore able to make determinations at temperatures far below its boiling-point. He also made the following suggestions:—

1. In order to eliminate the troublesome element of the tension of mercury vapour (without using two tubes as Grabowski did), heat the column to the required temperature, note its height, then allow it to cool, introduce the substance and heat again to the *same* temperature till the height is constant. To ensure uniformity of level in the bulb, keep it full to overflowing.

2. Before the first reading of the mercurial column a small piece of thin glass is passed up to liberate any air that may be contained in the mercury.

3. To make a mark on the tube a little above the vacuum mercury level and then only to calibrate about 150 mm. down from that point; then, to find the total volume, add the variable volume below the mark to the fixed volume above the mark.

Muir and Suguira,[2] in 1877, finding that sometimes the weight of the inner tube caused the groove in the india-rubber disk to so far close as to prevent the escape of the mercury while heating the substance, used a plain india-rubber disk which was fastened to the bottom of the trough, a disk of cork intervening. Communication between the mercury in the tube, and that in the trough was maintained by means of a short piece of glass tubing bent at right angles. A second tube long enough to stand slightly above the level of the mercury in the trough served to carry off, from the space between the two tubes, the condensed liquid and excess of vapour. They adopted Hofmann's original method of passing the steam in at the top of the outer tube, but used a small tube passing through a perforated cork in preference to one fused to the end.

Brühl [3] has, this year, proved by most carefully conducted experiments that the Hofmann method cannot be used above 220° owing to the great and rapidly increasing vapour-tension of mercury, but has omitted the grave objection to his own method. Playfair and Wanklyn [4] called attention, in 1861, to the fact that Bineau,[5] in 1846, pointed out that in vapour-density methods at very reduced pressures slight errors in the readings of the mercurial level introduce very serious errors into the result; this remark also applies to Croullebois.

In the overflow methods, which are in reality modifications of the Gay-Lussac, seeing that they are performed with known weights of substance, the first name is Hofmann,[6] who, in 1860, gave a very meagre description of his apparatus, when he wrote that he used a U-tube heated in a paraffin bath, and estimated the volume of the vapour by the mercury expelled. Wertheim,[1] in 1862–64, in his papers on Coniin, gave very full details of his method, in which he used two tubes suspended side by side in a flask.

Watts,[2] in 1867, employed a globe with a ground neck, into which an outlet-tube reaching nearly to the bottom of the globe was accurately fitted. The globe being filled with mercury and the substance introduced, the quantity of mercury expelled on heating served as a basis for calculating the volume occupied by the vapour. Victor Meyer,[3] in 1876, introduced two very important alterations, he avoided the vapour-tension of mercury by using fusible metal and placed the outlet at the bottom of the bulb. His experiments at that time were all made in the vapour of boiling sulphur, but Graebe,[4] last year, wishing to employ a higher temperature, used phosphorus pentasulphide, which boils at 530°.

Frerichs,[5] in 1876, used mercury in an apparatus similar in principle to that of Watts's, but employed an inverted flask, and brought the exit-tube, which was furnished with an inverted syphon, through a suitable outlet in the bottom of the bath.

Goldschmiedt and Ciamician,[6] in 1877, used mercury with the simpler bulb of Victor Meyer, but added a small side-tube to the outlet, so that the mercury expelled could be weighed from time to time during the heating. Victor Meyer,[7] in the same year, modified the shape of the bulb, but heated it in a tube similar to that employed by Greville Williams in Gay-Lussac's determinations, but of sufficient length for the upper part of the tube to serve as condenser.

Pfaundler's method,[8] of which a preliminary notice appeared in 1870, but which was not brought prominently forward till this year, is based on the increased tension of the air in an elongated bulb produced by heating after the introduction of the substance as compared with a similar determination on air in a bulb of the same size. A very short description appeared in 1874 of a method devised by Dulong [9] which is based on the same principle.

Last year Hofmann [10] proposed two methods; in one of these he heated the weighed substance over mercury in the closed limb of a U-tube, and marked the level of the mercury in the open limb by sliding a pointed tube through a loosely fitting perforated cork until it touched the surface. When the apparatus was cool, the volume of the vapour was calculated from the weight of mercury required to restore the level to that same point. The other consisted in introducing into a tube a small but weighed quantity of substance, then exhausting it and sealing it, and heating in a jacketed tube. At the required temperature the point of the glass tube is opened to allow air to enter, and then at once sealed again. After cooling, the point is opened under mercury or water, and the volume occupied by the vapour is measured.

In Meyer's [11] method, which is so recent and well-known as not to require any explanation, the principle is that of Pfaundler's, but by having the neck elongated and the outlet as a side-tube, the substance is introduced *after* the bulb is heated to the required temperature, and by allowing the air expelled by the vapour free egress into a graduated tube, it can be measured under atmospheric conditions. It is, therefore, so simple that the operation only requires a very short time from first to last.

Dewar and Scott [12] have lately determined the vapour-densities of potassium and sodium in a modified form of Meyer's apparatus.

In this sketch I have purposely kept off the very enticing ground of *formulæ*, as they of themselves open up so wide a field that they could not be dove-tailed into the history of the subject, which from *any* point of view is interesting.

ELECTRICITY AS A MOTIVE POWER[1]

THE lecturer commenced by referring to the stagnation of trade, to the various remedies that had been proposed to relieve it, and to the fact that while some were maintaining and others stoutly denying that commercial depression could be cured by legislation, we were too apt to forget that there existed a means by which, without lessening the wage of the workman or the profit of the master, the cost of production could be diminished, prices lowered, and the failing trade of England resuscitated. He next considered the consumption of coal for various purposes yearly in Sheffield, and showed that, although the price of coal in that town was very low, being only five shillings per ton for steam coal, the total annual cost for Sheffield alone must be something like 790,000*l*. Actual instances were then given of great saving being effected by water-power being employed on a large scale for doing mechanical work. Contrasted with this, calculation showed that at the Falls of Niagara as much power was wasted as could be produced by the total present annual consumption of coal throughout the whole world. And when it was remembered that there existed in the world other waterfalls besides Niagara, that we had also innumerable rapidly-flowing rivers, the important fact, well known to scientific men, but one which it was so difficult to induce the world at large to grasp, stared us in the face—that we obtained in a laborious way from the depths of the earth the power we employed, and we let run to waste, every hour of our lives, many, many times as much as we used.

Again, even in a perfectly flat country, where waterfalls were unknown, the question of the economic transmission of energy had no less interest, for large steam-engines could be worked much more economically than small ones, large steam-engines requiring a consumption of only two, or two and a half, pounds, of coal per horse-power per hour, whereas small steam-engines burned eight or ten pounds, or even more. And even where large economical engines were employed there was often, as in the gigantic cotton-spinning mills in Manchester, an enormous waste of power in the shafting used in transmitting it from the engine at the base of the factory to all the different floors, and parts of each floor, a waste so great that, in spite of the extreme inefficiency of small engines, it had been proposed, as an economical measure, to replace the one large steam-engine by many small ones, each driving two or three machines direct.

The lecturer then proved numerically that (contrary to the views expressed by some people) it was impossible to use economically in a town, for motive power, the water already brought in pipes to the houses for drinking purposes, since in most towns power so produced would cost about one shilling per horse-power per hour, and although in Sheffield the great head of the water would diminish this to about fivepence per horse-power per hour, still this had to be compared with considerably less than one farthing per hour the low cost in Sheffield of producing each horse-power with a very *large good* steam-engine.

Experience was leading us to see that it was to electricity that we must resort to obtain a carrier that would, at a small cost, transport our motive power over long distances, and as an illustration that the electric transference of energy on a large enough scale to be of practicable value was possible, knives were ground on the platform by power conveyed about a quarter of a mile through wires carried over the houses, a Siemens's dynamo machine being employed at the one end to convert into electricity the motive power supplied by a steam-engine, and a similar but smaller Siemens's dynamo machine being used on the platform at the other end to reconvert into motive power the electric current conveyed by the wires.

The principles on which dynamo-electric machines and electro-motors act were then entered into fully experimentally, and reference was made to the first electro-motor ever made—that constructed by Salvator del Negro in 1831—as well as to the improvements introduced into it by Jacobi, who replaced the oscillating motion by a rotatory one; different forms of modern electro-motors were then shown in action driving sewing-machines, &c. It was mentioned that although Jacobi abandoned his electro-motor used to propel a boat on the Neva because the fuel cost too much, still, that the subject of electro-motors was none the less practically important because we had since learnt why the old form was such an expensive producer of power, and what was the proper duty to be performed by electro-motors.

It was this very question:—Can an electric engine be made to work more economically than a steam engine? that first attracted Joule, of Manchester, in 1843, to commence that all-important investigation, which lasted for six years, the determination of the mechanical equivalent of heat.

Formerly, electric currents were almost entirely produced by galvanic batteries, in which zinc was burnt just as in the furnace of a steam engine coke was burnt. The amount of heat that could be got from burning a pound of zinc could be ascertained in the same way as the amount of heat produced by the burning of a pound of coal, but the fact that the latter was about seven times the former was of little value in the science of electro-motors, until Joule had proved that a certain quantity of heat was always equivalent to exactly the same quantity of work, no matter how the heat be produced; had proved in fact that energy was as indestructible as matter, a law which had for one of its proofs the long unsuccessful search for a perpetual motion.

As a result of this law of the conservation of energy Prof. Ayrton went on to show that since a pound of ordinary coal burning gave out seven times as much heat as the burning of a pound of zinc, we might say at once, that a steam engine would give seven times as much work as an electric engine for equal weights consumed, if in both cases all the heat could be turned into work; or, since zinc was about twenty-four times as dear as coal, that a steam engine would be about 150 times as economical as an electro motor, worked by a battery, if in both cases all the heat were converted into work.

But so far, he said, "we have only considered the law of 'Conservation of Energy.' There is, however, another, and no less important, principle called the 'Dissipation of Energy;' and this law tells us that although the energy of a system cannot by itself increase or diminish, yet our power to convert one form of energy into another is continually growing less, onr stock of available energy is gradually failing. Our mountain lakes, our vast store of coal, are practically useless until either the water is set in motion rolling down the hillside, or until the particles of the coal are set in rapid vibration as it slowly burns; energy of position, energy of chemical affinity, are of no use to the manufacturer until turned into kinetic energy or energy of motion. But from friction of various kinds, whenever energy exists in the kinetic form, some portion of it is being continually converted into heat. Whenever man or nature utilises energy it must be first turned into some kinetic form, and whatever be the aim of the special machinery employed some of this energy passes into heat. We cannot make even a clock go without regular winding up, although the only useful work done by the clock is to turn its hands at regular speeds; the earth's energy of rotation is now, like the moon's in past ages, gradually growing less, and is being converted into heat on account of tidal retardation; the earth, moon, and sun, and all the planets are losing their energies of motion and relative positions, to be all ultimately turned into heat.

"But at any rate, it will be said, there will still remain the heat, and since heat can be converted back into other forms of energy, we shall be none the worse off. But it must not be forgotten that whenever heat is produced some passes off by conduction through even our best non-conducting substances, and by radiation into space from even our best non-radiating surfaces; and this conducted and radiated heat, although it may impart some trifling warmth to unseen worlds, is for the greater part entirely lost to our universe. And even were it not so, even had we perfectly non-conducting coatings, and perfectly non-radiating surfaces—had we, in fact, the most perfect heat engine that our study of the science of heat would lead us to believe theoretically possible, one with no friction, no loss of heat by conduction through the sides of our cylinders, and no radiation from their surfaces—still our power to convert heat into other forms of energy would be very limited. For if there are two bodies, one hotter than the other, we can employ an engine, like a steam-engine, to convert part of the heat in the hotter one into some other form of energy; but the amount of heat converted, with even this ideal perfect engine, will, with such temperatures as are met with in practice, only be a fraction of what necessarily passes through the engine from the hot body to the cold, and warms up the latter; and as our whole power of conversion of heat into work depends on the difference of temperature, we lose it altogether when we have brought all parts of a system to the same temperature, no matter how high this temperature may be.

"It is not, therefore sufficient to say that the burning of a pound of coal produces seven times as much heat as the burning of a

[1] Abstract (by the author) of the British Association lecture delivered to 4,000 of the working-men of Sheffield, August 23, 1879, by Prof. W. E. Ayrton.

pound of zinc; but we must consider what fraction of the heat thus produced is converted into useful work in a heat and in an electric engine respectively.

"As already mentioned, our most perfect steam-engines can be made to produce one-horse power with the consumption of 2 lbs. of coal per hour. Now, the burning of 2 lbs. of coal will produce enough energy to raise 18,528,000 pounds one foot, or will produce 18,528,000 foot pounds of work. Now, one-horse power is equivalent to 1,980,000 foot pounds of work per hour; therefore, as regards the total energy in coal, even our best steam-engines only utilise $\frac{2}{9}$ of it, and waste $\frac{7}{9}$. But, as already mentioned, even a perfect engine cannot, with the ordinary temperature available, utilise the whole of the heat of the fuel. In fact, theory tells us that the efficiency of a perfect heat engine, or the ratio of the work done to the maximum work obtainable from the consumption of the fuel, is equal to the ratio of the number of degrees of temperature through which the steam is cooled in doing work to the highest temperature of our steam, when we take as our zero of temperature a point 460° below the ordinary zero of the Fahrenheit scale.

"Now, in our best steam-engines, the steam, when it begins to push the piston by expanding, has a temperature of about 300° F., and at the end of the stroke a temperature of 100° F., so that the efficiency of a perfect ideal engine working between these temperatures is only about $\frac{1}{4}$, not so very much greater than that of best practical engines.

"No great advance can be made, then, in a heat engine, except by making the temperature of the working substance, steam, gas, or whatever it may be, much higher. If, for example, we could raise the temperature of the working substance as high as, say, 3,000° F., the temperature of combustion, and could make it leave the engine without artificial cooling at the ordinary temperature of the air, which is, say, 60° F., then a perfect heat engine, under these conditions, would only waste about $\frac{1}{7}$ of the total energy; consequently, assuming that we could, at these high temperatures, make a practical engine as good relatively to an ideal perfect engine as we can at lower temperatures, then a practical engine would only waste $\frac{7}{43}$ of the total energy, or would have an efficiency of about 0·84.

"But, with our present knowledge, to work with steam or gas at a temperature of 3,000° F. is almost as ideal as an engine with no friction and with no loss of heat by conduction and radiation. We are, therefore, led to the conviction that as it is solely by working with steam at very high temperatures that the efficiency of steam-engines can be seriously increased, it may be well to consider whether it is not possible to economically replace the steam engine with some other form of motor."

It was then proved theoretically and experimentally that whenever an electro-motor is being worked by an electric current it is acting as a magneto-electric machine and producing a reverse current tending to stop the motion.

The lecturer then explained that, when an electro-motor is worked by a *given* galvanic battery, calculations lead us to the result that if we wish to produce the work *most economically* we must, by diminishing the load on the motor, allow its speed to increase until the reverse current it produces is only a little smaller than that sent by the battery; in fact, until the current circulating through the arrangement is very small, in which case the efficiency of the engine, or the ratio of the work it produces in a given time to the maximum work it could produce from the same consumption of material is nearly unity. If, on the other hand, we desire a *given* battery to cause the motor to do work *most quickly*, independently of the consumption of material, then calculation tells us that we ought to put such a load on the motor that its speed will send a reverse current equal to something like a half of the strength of the current the battery could send through the motor when at rest. In this case the efficiency is about $\frac{1}{2}$, or half the energy is wasted in heat.

He impressed upon the audience that the difference between these two considerations of maximum values ought carefully to be borne in mind, especially as it was usually the second—or how to obtain work *most quickly*—that had generally been taken into account, whereas it was the other one—or how to transmit work *most economically*, that would specially engage their attention during the lecture.

And in connection with the latter maximum value he said, "Let us consider that we work our motor in the most efficient way—that is very fast with a small load, and let us suppose as an extreme case that by so doing the efficiency is so little short of unity that we may regard it as one; then since an electro-motor worked by a battery in which zinc is burnt is 150 times as costly to maintain as a steam engine for equal efficiencies, the best electro-motor worked by such a battery will be thirty-three times as dear as our best steam engines having an efficiency of $\frac{2}{9}$. We may, therefore, throw on one side at once all idea of electro-motors worked by ordinary batteries, even although the electro-motors be perfect. Now, this result is most important, since it shows not that an electro-motor as a machine is inefficient, but it tells us that attempting to drive it with a galvanic battery is the hopelessly inefficient part of the arrangement.

"But if we turn to the question of using electro-motors for the transference of power, then there is no difficulty about burning zinc, and the high efficiency of such motors is all important.

"For in the case of natural sources of power, such as waterfalls, we have merely to consider what amount of energy will be produced at the distant factory; will it be sufficient to repay the expense of putting up wires from the source to the factory, together with the cost of the two dynamo-electric machines, or will it be cheaper to put up and use a small steam engine having probably an efficiency of only $\frac{1}{18}$?

"When the distance between the source and the motor is considerable, the cost of putting up the leading wires becomes important, and the question therefore arises, can two or more people use the same leading wires without increasing the thickness, or must the thickness of the wire be so much increased as to make the construction of two sets of leads as economical?"

Prof. Ayrton explained that he attached great importance to this question because the answer to it would decide whether the electric transmission of power was a mere dreamer's fancy, or was likely to have a real commercial future.

A detailed examination was then made of the laws governing the transmission of energy by water power, and as a result of the fact that the energy of a flow of water depends on the quantity and on its head it was shown that, as far as the waste of power by friction of the water in the pipes was concerned, a great pressure in the reservoir sending a small current to turbines in a town also working at great pressure was an extremely economical mode of transporting power, but that if we took into account the inefficiency of existing engines for producing a great pressure of water at the reservoir, combined with the great waste of power arising from even small leakages that were certain to be caused by the great water pressure, it followed that the system was an impracticable one.

An examination was then made of the laws governing the electric transport of energy, and the lecturer arrived at this result:—

"Just as we concluded in the case of the water, that the most efficient method to employ in order to transfer the energy, was great pressure in the reservoir, combined with turbines in the town working at a high pressure, so now we conclude that the most efficient way to transfer energy electrically is to use a generator producing a high electromotive force, and a motor producing a return high electromotive force; and by so doing the waste of power in the transmission ought, I consider, be able to be diminished with our best existing dynamo-electric machines to about 30 per cent.; for, as experiment shows the efficiency of our best existing dynamo-machines to be 0·86 (that is 86 per cent. of the power spent in revolving the bobbins is reproduced as energy of electric current); therefore, if two similar dynamo-electric machines be coupled up to transmit power, and if they are worked most *economically* in the general way I have already explained, and with the details of arrangement that I will enter into later on, instead of being worked so that the motor gives out power *most rapidly*, I have reason for expecting that the combined efficiency of the arrangement can be made to closely approach the square of 0·86, and not merely one-half, as commonly supposed.

"But while the two solutions of the problem are thus identical, there is this most important difference: increasing the pressure of the water means an uneconomical task, while increasing the electromotive force set up by a dynamo-electric machine, or an electro-motor, means merely running it faster, or running it at the same speed and putting more wire on the rotatory portion.

"And again, assuming that the mean electromotive force between the wire and the earth be as much as one hundred times the electromotive force producing the current, namely, the difference between the electromotive forces of the generator and of the motor, then with the ordinary insulation of the best land telegraph lines, less than one per cent. of the energy transmitted ten miles would be lost by leakage.

"It would be impossible to increase indefinitely the speed of revolution of the cylinder of an induction machine, since apart from mere mechanical friction the iron constituting the core of the revolving part has to be magnetised and demagnetised very rapidly as it revolves. Now, there is a physical limit to the speed with which this can be done, and in addition this rapid change of magnetism heats the iron very much. But experiment shows that at the ordinary speed of revolution of dynamo-electro machines, 700 turns per minute, the electromotive force is proportional to the speed. We are, therefore, very far yet from the limit of speed. Consequently it would be well for the transmission of power to attempt first, a considerable increase of speed in the generator, combined with so light a load on the motor, that its speed is also very high. When this begins to fail as larger and larger amounts of power are transmitted, then we might begin increasing the amount of wire on the revolving coils of each; but this, of course, has the objection that the loss of power from a given current would then become somewhat larger.

"In some of the dynamo-electric machines, the current that is sent through the external wires is the same as that which circulates round the fixed electro-magnets to create the magnetic field in which the movable coils revolve. Now, the small current which I am here advocating should pass between the generator at the one end of the line, and the electro-motor at the other, would be too small to properly magnetise the fixed electro-magnets of the two machines, so that even a high speed of the bobbin will not produce a high electromotive force. But this difficulty is easily overcome by the plan already employed, for totally different reasons, by Gramme, Lontin and Wilde, in their generator for producing currents for electric lighting, viz., that of using either a separate exciter, or a separate portion of the revolving bobbin in the generator, to produce the current to magnetise the fixed electro-magnets. In connection with this current for exciting the fixed magnets, it is worthy of notice in passing, to observe that since experience shows that the electromotive force of a dynamo-electric machine is proportional to the velocity, I conclude that the magnets are saturated, and that the exciting current is already too strong, so that it may be with advantage reduced, or many fewer coils of wire employed in this portion of the machine.

"We have then been led to this most important result which I hope is clear to you all, and which I trust you may all carry away with you—*that a dynamo-electric machine, with a separate exciter, driven very fast with a steam engine, or with a stream of water, at high or low pressure, and sending, by even quite a fine wire, a small current to a distant electro-motor, also running very fast and magnetised by a separate exciter, is an economic arrangement for the transmission of power.*"

An examination was then made of the way this result was affected by increasing the length of the connecting wires, and it was proved that the electric transmission of power was not only practical, but also very economical, both for short and long distances, if the generator of the electric current at one end of the line and the motor, worked by this electric current, at the other end of the line, were both run fast enough, and if only we required to transmit a sufficiently large quantity of power.

The lecturer then went on to say, "We have been considering the transport of power derived more especially from natural sources; but since we have seen that by the use of electricity, properly employed, the waste of power in transmission can be reduced for any distance to about 30 per cent. of the whole power absorbed at the generator, it follows that the employment of steam-engines of vast size at points outside Sheffield would be by far the most economical mode of extracting the energy out of coal. For it is at least four times as expensive to produce power with a small steam-engine as with a large one; therefore, including the waste of power in electric transmission, the cost of production of power in small workshops would be little more than one-third as dear as if small steam-engines were used, and similarly the waste of power in any large mill or factory in its transmission from the large steam-engine at its base to all the floors and machines on each floor would be very much diminished.

"Consequently it would be much more economical to work this lathe on the platform, as I will now proceed to do, by a big steam-engine in Howard-street, several hundred yards away, than to use a small steam-engine here for this purpose."

He then reminded them that not only can electricity produce motive power, but also light and heat, and electric heating and lighting had this great advantage, that no chimneys were required. Experiments were then made of boiling water and lighting the Albert Hall by an electric current generated a quarter of a mile away.

Reference was then made to the great money-saving of something like 30*s.* an hour, that Dr. Siemens had been able to effect at the Albert Hall, London, by replacing the old gas jets by electric lamps giving even more light, and to the unexpected advantage attained by the present stillness of the air arising from the use of the electric light, and which enabled the singing and music there to be better heard now. Great weight was attached to the fact that at the Albert Hall the science of hanging a brilliant light high up had been luckily allowed to ride over the precedent of putting a number of feeble glimmers all over a building, and in connection with this it was explained that the reason why electric lighting for streets had been economically much less successful, was because English conservatism had prevented the authorities from realising the possibility of using for street electric illumination anything differing from an ordinary iron lamp-post. Attention was then drawn to the fact bearing most closely on the economy of electric lighting on a large scale, and which had been obtained as the result of experiments, that the larger were the dynamo machines used for producing the electric light, the more light was produced per horse-power. Taking all this into consideration, Prof. Ayrton arrived at the result that "at any rate we may be absolutely safe in saying that the cost of using gas in Sheffield for lighting large halls, such as the one we are now in, factories, and the streets could be halved if electric currents, generated by water engines worked by hill streams, as well as by very large steam engines, were substituted for gas.

"But can this be quite right, for I have proved that to transfer energy economically we must use a large pressure and a small flow. Now, how can we produce a very bright electric light with a small current? Why, by not using the current that comes along the wire to produce the light at all, but merely to drive an electro-motor, which motor, at the place where any large amount of light was required, would be employed in giving motion to a second dynamo-electric machine, which would produce the currents for lighting purposes.

"This experiment I might show you, but as we have used already several times during the evening electric lights fed from a distance, we will vary the experiment and try an analogous one. Messrs. Walker and Hall will now, at their works, give rapid motion to a dynamo-machine, and the current which, when properly arranged, as I have explained to you, may be small, will set in motion this electro-motor. This in its turn will cause this other dynamo machine to rotate rapidly and produce a current which I will use for rapidly gilding this piece of plate."

Calculation showed that if electric currents generated by very large steam engines at certain points, and by turbines driven by the falling water on the hillsides round Sheffield, were substituted for the use of coal for motive power, smelting, heating, and lighting buildings, that a saving of something like 400,000*l.* a year might be anticipated for that town; and as an argument to prove that although such a reform was startling in its economical bearing, it might nevertheless be sound, the following was adduced:—Imagine the cost of cutlery and plated goods to remain as at present, but all machinery to be removed from Sheffield, then what an enormous loss would accrue to the town from everything having to be done by hand labour. The saving then which the lecturer was showing the audience how to obtain, enormous though it might be, was still small compared with the gain that the introduction of machinery during the last hundred years had effected for that town.

Next was considered whether the Sheffield Water Company had any water in their reservoirs that could be spared for producing motive power, since of course the water which did work at its source would lose head and so be unable to come to the tops of the houses in the town as at present, and it was shown that there was a considerable surplus supply. As an illustration of such a use of the water power, a two inch board was sawn on the platform by a circular saw, driven by an electric current generated by a water engine in the yard of the Water Works, and conveyed to the Hall by wires crossing the streets.

As a practical illustration of what had been done the lecturer said:—"Last year two French engineers, MM. Chrétien and Felix, at Sermaize (Marne), actually ploughed fields by electricity, the electric current being produced by two dynamo-electric machines, of a form invented by M. Gramme, and shown in the diagrams on the walls. These machines were usually worked

with a steam engine at some convenient place three or four hundred yards away in an adjoining road, and the electro-motors were also two Gramme machines, one on each side of the field, with their coils revolving of course backwards. Through one of these, the electric current was sent alternately, so that motion was given to one or other of two large windlasses, one on each of the waggons containing the electro-motors. In this way the plough, which could be used going in either direction, was first pulled across the field making a furrow, and then back again making another parallel furrow."

A photograph taken on the spot, of one of the complete Gramme electro-motors, with its windlass and waggon, together with the double acting plough, was projected on to the screen.

A second photograph was also now projected on to the screen of M. Chrétien's electric crane for unloading boats. This too, the lecturer said, had been successfully employed for several months at Sermaize, in the harbour there, and it was considered that a saving of about thirty per cent. had been effected of the expense formerly incurred for unloading the sugar barrels out of the boats.

Reference was then made to the difficulty that would be experienced in distributing electric power properly on account of the current in any curcuit being affected by any alteration in any other circuit connected with it, and it was explained how this difficulty was met by the electric current regulations of M. Hospitalier and Dr. Siemens. Another difficulty arising from the velocity of the water on the hill streams being great after floods and small in dry weather, and which at first sight might appear to require an extravagant supply of dynamo machines so that even in a draught sufficient power could be transmittted electrically, it was explained, could be overcome by storing up the electric energy as compressed gas, and it was shown that a square foot of hydrogen at thirty atmospheres pressure (the usual pressure in the iron gas bottles of commerce) combining with half a cubic foot of oxygen, at the same pressure, would develop no less than 110 million foot pounds of work.

Prof. Ayrton concluded by asking:—

"But is there no other side to this question? We are, it is true, a commercial people, but do we not still love our hills and our fields? There was a time when the cutler of now black, grimy, Sheffield was very fleet of foot in following the chase. There was a time when 'Not only in the villages around old Sheffield,' so says the history of Hallamshire, 'were the file-makers' shops or the smithy to be seen, with the apprentices at work; but even on the hill side in the open country, at the end of the barn would be the cutlers' shed whilst in the valley below, by the river, was the grinding wheel ready to sharpen the tools that had been manufactured.'

"And why not now? why should not that mountain air that has given you workmen of Hallamshire in past times your sinew, your independence of character, blow over your grindstone now? Why should not division of labour be carried to its end and power brought to you instead of you to the power? Let us hope then that in the next century electricity may undo whatever harm steam may have done during the last, and that the future workman of Sheffield will, instead of breathing the necessarily impure air of crowded factories, find himself again on the hill side, but with electric energy laid on at his command."

THE ANTIQUITY OF MAN

AT the Sheffield meeting of the British Association Prof. Boyd Dawkins, in the course of a paper "On the Antiquity of Man," said he presented before them a diagram showing the divisions of the tertiary period, the third of the three great life periods which had been presented on the earth. When he examined those stages before the highest forms of life, he was confronted with this most important fact: in the eocene age they had not a single species of placental mammal, nor did they meet with any indications of a living placental genus. No species now found in Europe were found in the eocene age. It was absolutely impossible to suppose that man was living on the earth in eocene time, yet there was no reason, because of climate and vegetation, that he should not have been. Then they came to the miocene age, when they found not merely living families and orders, but living genera. Putting man out of the question, there was not a single well-authenticated case on record in any part of the world of any mammalian species now living on the earth having lived in the miocene age. The French preserved a flint flake which was found at Thenay, and which they say is of the miocene age; in fact it was accepted by a great majority of the French archæologists that man was living in the miocene age. The French held that flints found, and all of them bearing traces of manufacture, were of the miocene age, and the work of man. It was far less difficult to believe that these flints were the work of some of the higher and extinct forms of mokeys, than it was to believe that they were the work of man. In the pliocene age they found one or two living species making their appearance. Prof. Capelini had called attention to the fact that certain cut bones, which were asserted to be of the miocene age, had been cut by the hand of man. On one of those bones there were cuts which were done by the hand of man. The cuts were distinctly artificial, but the difficulty which presented itself to his mind was this. He was by no means certain that those bones, which were said to have been found in the pliocene strata, had been discovered in undisturbed pliocene strata. It was not clear to his mind that the mineralisation of those bones would not take place long after the pliocene age had passed away. He urged his objections to the accepting of specimens said to have been got in the pliocene age when there was no good authority for saying that such was the case. He then passed to the pleistocene, by some called the glacial period. Then living species were very abundant, extinct species very rare, and it was in that age that they met with man in considerable abundance and scattered over a very wide area. The evidence presented from time to time, in the first place out of caverns, and on the other hand out of river deposits, showed beyond a doubt that man was present in Europe in full force in the pleistocene age, and he came in just when it might be expected he would come in. In the pleistocene age they met with man as a mere hunter, not as a farmer or possessor of wild animals. He mentioned that because during the last two or three years it had been asserted that man was possessed of domestic animals in the pleistocene period. The pre-historic period which succeeded the pleistocene, was characterised by the absence of the extinct species of mammalia, with one exception. The one extinct animal which extended upward into the pre-historic age was the Irish elk. The great characteristic of the pre-historic age was the calling in of the domestic animals, the dog, sheep, horse, various breeds of hog, cattle—all coming in under the care of man, all spreading over Europe; and along with them they had the getting of cereals and fruits, and the cultivation of the arts of agriculture. They had in that period just those very things which formed the foundation of that civilisation which they themselves spread, and which had been built upon the foundations of the neolithic age. The pre-historic period was divided into the neolithic, the bronze age, and the age of iron. The pre-historic age was divided from the historic, because the former was not represented to them in historic records. In conclusion he ventured to express an opinion as to how happy they would be if they could get hold of a date and fix the antiquity of man in Europe in terms of years. It would be most delightful if they could fix the first presence of man at Creswell Crags, say within some thousands or hundreds of thousands of years. He could not help thinking that all their hopes of that description would be vain, as there were intervals, and they could not know without the written record, the duration of the intervals which separated one period from another.

UNDERGROUND TEMPERATURE[1]

THE temperature of the surface of the ground is not sensibly influenced by the flow of heat upwards from below, but is determined by astronomical and atmospheric conditions. The rate of increase in travelling downwards from the surface may conveniently be called the *temperature gradient*, and averages about 1° F. for fifty or sixty feet. This is about five times as steep as the temperature gradient in the air.

If we draw isothermal surfaces for mean annual temperature in the ground, their form beneath mountains and valleys will be flatter than that of the surface above them. This is true even of the uppermost; and the flattening increases as we pass to lower ones, until at a considerable depth they become sensibly horizontal planes. The temperature gradient is consequently steeper beneath gorges and least deep beneath ridges.

In a place where the surface of the ground and the isothermal surfaces beneath it are horizontal the flow of heat will be vertical,

[1] "On some Broad Features of Underground Temperature," by Prof. J. D. Everett, F.R.S. Abstract of paper read at the Sheffield meeting of the British Association.

and the same quantity of heat will flow across all sections which lie in the same vertical. In this case the flow across a horizontal area of unit size will be equal to the product of the *temperature gradient* by the *conductivity*, if we employ the latter term in an extended sense so as to make it include convection by the percolation of water, as well as conduction proper. It follows that in comparing different strata lying in the same vertical, the gradient will vary in the converse ratio of their conductivity. It seems probable that the same law of inverse proportion between gradient and conductivity holds approximately even when the strata compared are not in the same vertical but are widely distant.

As regards the modes of observation which have been employed for the determination of gradients:—shafts full of water, and wells of large diameter, afford so much facility for equalisation of temperature by currents between the colder water above and the warmer water below, that they furnish no useful results. Even in bores of small diameter the same disturbing cause exists and always makes the observed less than the true gradient.

Observations in mines will be vitiated by the presence of pyrites, which generates heat by its slow combustion, and are also liable to be vitiated by strong currents of air; but when they are taken at the newly exposed face of a gallery which is being driven into the rock, care being taken to prevent strong air-currents at the place, and the surrounding ground not being too much honeycombed by previous excavations, good results may be obtained. A hole should be bored to the depth of about two feet in the newly exposed face, the thermometer inserted, and the hole plugged with clay.

SCIENTIFIC SERIALS

American Journal of Science and Arts, September.—In the opening paper, on the pertinacity and predominance of weeds, Prof. Asa Gray, from an examination of European weeds which have taken a strong hold on the United States, opposes Mr. Henslow's view that plants best fitted for domination as weeds are in general self-fertilised plants, and owe their predominance to this. He also regards the "greater plasticity" assumed by Prof. Claypole for European as compared with American plants as purely hypothetical.—In view of the variations in amount of oxygen in the atmosphere of a given place (sometimes by as much as one-fortieth of the average, and often the one-hundredth or two-hundredth part), Prof. Morley calls in the theory by which Prof. Loomis accounts for certain great and sudden depressions of temperature at the earth's surface, viz., by vertical descent of cold air from the higher parts of the atmosphere. The lower air at such times might well contain a less proportion of oxygen than the average. Pending systematic observations at points Prof. Loomis has indicated, the author here describes at length his method of analysis, and the results of observation on samples of air collected at home; these seem to lend some support to his theory.—A remarkable meteorite fell at Estherville, Emmel Co., Iowa, on May 10; one mass weighing 431 lbs. was found fourteen feet under the surface of the ground in a ravine, and, besides several small masses near, a mass of 151 lbs. about two miles westward. Prof. Shepard, from specimens in hand, regards this meteorite as a connecting-link between the litholites and lithosiderites, unless it be placed as a separate order in the Eucritic group of the former.—Prof. Marsh announces the discovery of two new lower jaws belonging to the genus *Dryolestes* (of Jurassic mammals).—Remaining papers:—On the colour correction of achromatic telescopes, by Mr. Harkness.—Reply to Principal Dawson on *Eozöon canadense*, by Prof. Möbius.—Terminal moraines of the North American ice-sheet (continued), by Mr. Upham.—New observations on planetoids, by Mr. Peters.—Observations on the genus Macropis, by Mr. Patton.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, September 29.—M. Daubrée in the chair.—The following papers were read:—On the development of the perturbative function in the case where, the eccentricities being small, there is any mutual inclination of the orbits, by M. Tisserand.—Construction of the international geodetic standard, and determination of its controlling weights, by MM. Sainte-Claire Deville and Debray. The method is given in detail.—Studies on the effects and mode of action of substances employed in antiseptic dressings, by MM. Gosselin and Bergeron. The method was to put blood, then pus, in contact with various antiseptic agents (including solutions of carbolic acid of various strength, camphorised alcohol, camphorised brandy), and noting the effects, both with the naked eye and with the microscope. The antiseptic agent was in some cases put in glasses with the blood or pus, sometimes applied by means of evaporation and pulverisation. The result is specified in each case; the 20 per cent. solution of carbolic acid, alcohol, and camphorised alcohol, seem to have prevented putrefaction best.—Theoretical essay on the law of Dulong and Petit; case of solid and liquid bodies and vapours, compound bodies, by M. Willotte.—Vibratory forms of bubbles of glyceric liquid, by M. Decharme. A bubble is supported on a thin watch-glass fixed at the end of a vibrating plate or rod; it follows and amplifies the vibrations, and with favourable conditions one can see distinct nodes and ventral segments, whose number varies with the velocity of vibration and diameter of the bubble. Three laws are given: (1) With a given number of nodals, the diameters of the bubbles are proportional to the lengths of the vibrating plate, or inversely proportional to the square roots of the numbers of vibrations. (2) With a given diameters of bubbles, the numbers of nodals are inversely proportional to the lengths of the vibrating plate, or directly proportional to the square roots of the numbers of vibrations. (3) With a given length of vibrating rod, the numbers of nodals are proportional to the diameters of the bulbs. These experiments generalise that of Melde by extending it to spherical surfaces, and even to volumes, for the author has found that thin balloons of caoutchouc filled with water behave like bubbles.—On the presence of alcohol in the animal tissues during life and after death, in the case of putrefaction, from the physiological and toxicological point of view, by M. Bechamp. Horse-flesh (3 kg.) plunged for ten minutes in boiling water, to coagulate the surface, then inclosed in a vessel, was examined after a month. About 0·8 gr. of alcohol was got from the interior, and 10 gr. of salts (acetate, butyrate, &c.) of soda. (There were numerous bacteria; no vibrion.) 4 kg. left to itself four days gave less alcohol. Thus putrefaction is essentially similar to fermentation; and specially so to butyric. M. Bechamp also found alcohol in various healthy animal tissues (brain, muscles, and liver).—Action of sulphide of carbon liberated in a slow and prolonged way on the vine, by M. Rohart. This is more efficacious than the brief application, and does not injure the plant.—Discovery of two small planets by Mr. Peters.—Action of metallic nitrates on monohydrated nitric acid, by M. Ditte.—Thermal study of succinic acid and its derivatives, by M. Chroustchoff.—On a new curare extracted from only one plant, *Strychnos triplinervia*, by MM. Couty and De Lacerda. This is less active than the other, but easy to obtain in large quantity. It gives in a few seconds a curarisation which may be arrested in its different periods.

POLAR ICE

Die Metamorphosen des Polareises. Von Karl Weyprecht. (Wien, 1879: Moritz Perles.)

THIS book of Karl Weyprecht's is a most valuable outcome of the Austro-Hungarian Arctic expedition of 1872–1874, so well known already from the interesting general popular account of the doings of the expedition which has been published in most European languages. In the present work the author confines himself to an account of the phenomena presented by the ice amongst which he spent so many weary months. It might well be supposed that a book treating of such a subject only would be dull reading, but so graphic are Lieut. Weyprecht's descriptions, and so pleasantly are his long series of observations strung together into a continuous whole, that his book is most entertaining throughout, and the reader lays it down with a very much enhanced comprehension of the never-ceasing changes and mighty power of Arctic ice. Most of the facts recorded are known to Arctic explorers, and have been more or less set forth by them in their various writings, but no connected account of all the forms of the growth and death, of the movements and struggles of bergs and floes and ice of all forms has been before attempted Lieut. Weyprecht tells it us all from his own observations. The book is divided into a series of chapters headed as follows:—I. Various Forms of the Ice and their Origin. II. Ice-pressures. III. The Ice in Winter. IV. The Ice in Summer. V. The Changes of the Ice. VI. The Water Movement in the Polar Regions. VII. The Ice Movements. VIII. The Ice of the Arctic Interior.

In the first chapter he treats of the three different kinds of Polar ice: glacier ice, salt-water ice, and fresh-water ice. As an example of the mighty size of the Polar glaciers, the parents of the icebergs, he cites the Humboldt glacier of Smith Sound, which, pushing itself into the sea in Smith Sound, forms an unbroken ice coast-line composed of perpendicular cliffs 300 feet in height above the sea-level, and 60 miles in length, a single solid ice wall split only by vertical fissures. The fresh-water ice is clear as crystal, and so hard that the Norwegian walrus-hunters who run their small vessels in their voyages against all other ice obstacles, of whatever size, are careful not to charge even comparatively small pieces of this. This kind of ice is, however, scarce in the polar regions; it is the third kind of ice, that of salt water, or "field-ice," which forms by far the greater part of floating ice, and with which the book is mainly concerned. The *Tegetthoff* was shut in for a year in field-ice, and the author watched the incessant changes in the ice with great care throughout this period.

A simple smooth sheet of sea-water ice is no sooner formed than it begins to be subjected to a variety of influences, which speedily convert its smooth expanse into a complicated rugged surface, covered with ridges, valleys, and irregularities of all kinds, render its thickness everywhere unlike, and split it up with innumerable fissures. Most important amongst the causes of these changes are the variations of temperature to which the ice is exposed from the variation of that of the water below and the air above, and which are more or less local, and affect the ice differently wherever its thickness varies. From these differences of temperature ensue complicated strains in all directions, due to the unequal expansion and contraction of the mass, and the ice is rent by the tension; to these forces is added the pressure of surrounding ice-fields, driven by the action of winds or currents; long fissures are formed, the edges of which grind together with mighty force. After a while the edges separate, and the water between pulsates with the throbbing of the surrounding floes. Again they come together, and forced against one another with ever-increasing power, they are crushed and break up, huge blocks are piled above on the ice-surface, resting at all angles upon one another, and other huge blocks are forced under the ice below. Hence the ice becomes rugged above, and by the freezing to it of the blocks forced under water, equally so below, the variation in thickness is increased, and with it the amount of strains caused by variation of temperature. The drifting snow hangs against the ridges and pinnacles on the surface, and forms banks and mounds which not only increase the effects due to temperature by protecting the areas on which they lie from change, but also by their immense weight, combined with that of the projecting ice-masses by which they are formed, press down the ice which supports them, whilst the blocks below in other regions press it up. Throughout the mass gravity acts as a disturbant, no part being water-borne at its natural level, the mass is strained, and gives way in all directions, and fresh complications ensue.

All these changes are accompanied by a noise. The unlucky prisoner in the field-ice during the imposing unbroken loneliness of the long Arctic night, when the wind is calm, can hear the crackle of the snow under the stealthy tread of the Polar bear at an astonishing distance, and hear what a man, speaking loud, says at 1,000 metres distance. It can, therefore, be well understood how the sound of the ice-pressures must travel to his ear from enormous distances. "Sometimes," the author writes, "the noise of the ice movements was scarcely to be heard —a mere murmur—and came to our ears as does the play of the waves on a steep coast from the far far distance. Sometimes it hummed and roared closer to us, as if a whole column of heavily laden waggons were being drawn over the uneven ice surface." In the sound were combined all manner of noises caused by cracking, grinding, falling of blocks, crushing, and many other phenomena of ice-life. "It is astonishing how far and how clearly every noise is conducted in the ice. The noise at the very margin of the field on which we were seemed to occur immediately at our feet. . . . If we placed our ears to the ice the sound was heard so loudly that we might have expected the ice to open under our feet the next moment. The whole dry ice covering was as a vast sounding-board. Whenever, as I lay down to sleep, I placed my ear against the dry wooden ship's side, I heard a humming and buzzing which was nothing else but the sum of all the noises which occurred in the ice at great distance from the ship."

A curious fact is described by the author, that the surface of an expanse of young salt-water ice on which no snow has yet fallen is soft, so that the footstep is impressed upon its white covering as in melting snow. This is to be

observed even at a temperature of $-40°$ C. The unfrozen fluid is not water, but a concentrated solution of salt thrown out by the freezing of the ice beneath.

When summer begins, the thawing that occurs is very local and unequal. Any dark body, such as a heap of ashes or the droppings of bears, eats its way into the snow, absorbing the rays of heat which are reflected off again by the general white surface. The bear droppings eat their way into the snow, and then into the ice, and the conical hole thus formed fills itself with water. It may, at last, eat its way right through the ice where not very thick. Thus are formed the greater part of those holes in drift-ice which are usually ascribed to seals. The author never saw a seal's hole in winter.

A number of interesting experiments were made on ice phenomena. For example, on March 5, a cube of ice was sunk under the ice-field to a depth of five metres. After a lapse of twenty-four hours it was found that a crust of new ice had formed itself over it about 1 cm. thick. This was caused by the low temperature of the block itself and, from a similar cause, ice-crystals had formed between the edges of the hole, owing to the coldness of its walls. On March 10 very little increase in the added layer of ice on the cube was to be observed. On March 20 this newly-formed ice was found to be softened so that it was easily impressed by the finger; by April 2 it had become harder again, though porous and apparently a little increased. From thence onwards the block dwindled regularly, especially on that part of its surface which was turned upwards; on July 18 it was only a third of its original size; nevertheless, the hole through which it was sunk had, during the last period, become entirely closed by young ice at its lower margin. This experiment shows the loss of ice from below by the action of the warmth of the water. The author concludes from his experiments and measurements that compact salt-water ice can never attain a greater thickness than 10 metres.

Icebergs are subjected to disintegration after somewhat the same manner as rocks so commonly are. They are full of crevasses, into which the water formed by melting penetrates; in winter this water freezes, and by its expansion all through the glacier a rupture of the mass ensues. "It is highly probable that most of the icebergs afloat in winter are in such a condition that a very slight cause is sufficient to make them burst because of their state of internal tension. . . . Every polar traveller can tell how a shot, the driving-in of an ice-anchor, or any other sudden vibration, has brought about the catastrophe; cases have even occurred in which the sound of the voice alone was sufficient. An iceberg is always an unpleasant neighbour." So many are the causes which tend to destroy icebergs that the author concludes "no berg exists which could withstand them more than ten years, and that commonly the life of a berg is much shorter." However this may be, doubtless the much larger Antarctic bergs last very much longer, as must necessarily occur because of the much greater uniformity of the climate to which they are exposed.

With regard to glaciers, the author quotes an interesting observation of Kane's to the effect that even in lat. 78° 20′ during the entire winter, however low be the temperature, the glacier streams never dry up. The melting which supplies them with water can only derive its requisite heat from the friction of the ice-masses.

The chapter on the ice-movements is full of interest. Every field acted on by winds and currents has its own peculiar velocity, depending on the dimensions of the irregularities above and those of the resistances below, in which no two fields are alike. From these differences of velocity arise the irresistible pressures between contiguous fields. The iceberg deeply sunk drifts but slowly, whilst the ice-field may travel very fast. If the field catches up a berg in its course, it is broken and torn by the berg; and as it proceeds on its course its broken fragments are piled up block upon block on the coast of the iceberg. To a casual observer it appears as if the iceberg, driven by a counter current below, were being forced in the opposite direction to the ice-field, so as to plough it up. Many groundless accounts of the existence of such counter currents thus observed have been circulated.

Another cause of pressure between ice-fields is that, owing to the irregularities on their surfaces, they are twisted round by the action of the wind, which takes hold more on some regions than others. Every field is differently thus acted upon for each direction of the wind. A similar effect is caused by the currents beneath acting upon the irregularities of the under surface. So various are the movements in the ice-fields, that even when the ice lies all the while closed, it is very seldom that any two pieces remain for any length of time in the same position alongside one another. Two ships beset together by the ice are sure sooner or later to be separated.

The author fully admits that the danger incurred by explorers in the Antarctic regions is very much greater than that to which Arctic voyagers are exposed. The fog in the south is a terrible enemy, and there a ship cannot at once take refuge in the field-ice as in the north. He urges, however, the necessity for scientific Antarctic exploration and observation, and suggests that a wintering in the lands lying south of Cape Horn could be easily accomplished, and would not require any very extensive appliances. We fully agree as to the benefit to be derived by science from a round of meteorological observations and all other kinds of scientific exploration in the Antarctic regions, and heartily wish that such enterprise would take the place of the constant struggles to get to the North Pole. By the mere reaching of the pole there is nothing to be attained. A steamship could very possibly run down from New Zealand direct to Mount Erebus and Terror in a fortnight during the summer months; such an attempt has never been made. It need not be very costly, and possibly the Government of one of the Australian colonies may make it some day. We commend Karl Weyprecht's book to all who study ice phenomena, but not only to specialists, for it is full of interest to all intelligent readers. H. N. MOSELEY

THE SILK GOODS OF AMERICA

The Silk Goods of America. By Wm. C. Wyckoff. (New York: Van Nostrand.)

THIS book has been issued under the auspices of the Silk Association of America, with the view of affording information as to the character of the silk goods manufactured in that country. Not many years since

nearly all such goods were imported, and even now the entire product of many of the American silk mills is represented to the consumer as of European make. The Silk Association have, however, bestirred themselves; they find that in order to obtain a standing in a market where imported articles hold an established reputation they are obliged to make better fabrics than their foreign rivals, and, naturally enough, they now seek to secure for themselves the credit of their enterprise. The Centennial Exhibition startled the manufacturers both of this country and of France with the extent and rapidity of their progress in developing this special branch of industry. The railways across the Continent and the direct trade with Asia across the Pacific Ocean have placed America more nearly on a level with European countries as regards supplies of raw silk; improvements in the power-loom and the continuance of the tariff policy of the Government have done the rest. Mr. Wyckoff boldly states that had that policy vacillated during the last ten or fifteen years there would have been no story of improvement to tell.

One of the main difficulties with which the American manufacturer had to contend was the want of skilled labour, and this was more especially felt in the production of black dress goods. On account of the necessity of securing perfect equality in the threads, such goods are far more difficult to produce than are more highly ornamented fabrics, but although the manufacture of broad black silks on anything like a large scale has only been attempted in America during the last half-dozen years it is estimated that fully a third of the plain silks and a much larger proportion of the brocade silks which are consumed in that country are made there. Indeed Mr. Wyckoff states that the advance in this branch of manufacture within the last three years is greater than that in any other department of American silk industry. Nor is the reason for this far to seek. The American manufacturers, as a class, have studiously set their faces against the abominable system of "loading" which prevails so largely on this side the Atlantic. Nearly all European broad black silks are doubled, nay, sometimes even trebled, in weight in the dyeing of the yarn. This is how the "Black Art" is practised in France. The yarn is repeatedly dipped in nitrate of iron until sufficiently weighted, after which it is passed through a bath of prussiate of potash and then treated with gambier and acetate of iron. To brighten it it is next passed through a logwood bath and well soaped; if it is to be soft and satin-like it is oiled and treated with soda; if it is to be stiff and rustling it is dipped in acid. No wonder after this that the black silk with its load of grease and iron wears shiny, and cracks in the folds. "It is asking too much to demand that the few strands shall act as iron-mine, soap-factory, and chemical laboratory all at once and stand the wear of practical use besides. These are requirements before which the English attempt to make a grocery store out of a shirt pattern is a simple and ordinary matter." Nothing is easier, however, than to discover this loading of dye-stuff. If ladies would insist on being allowed to test a small sample of the silk, at home, before purchasing, by the very simple operation of burning it, the sophistication would speedily perish. Pure silk crisps instantly on burning, and leaves a small quantity of charcoal; loaded silk smoulders slowly to a yellow ash. Not many years ago men's coats were largely trimmed with black silk braid; but now, as a maker in the article was heard dolefully to declare, "the trade in black braids is as dead as Julius Cæsar," for we have naturally got disgusted with the frayed and brown appearance which the article generally assumes after a week or two's wear, thanks to the fact that it usually contains more dye-stuff than silk. The public is gradually awakening to a knowledge of these things, just as surely as the patient Hindoo and the heathen Chinee have had their eyes opened to that miserable compound of starch, cotton, China clay, and Epsom salts which the Manchester merchants have palmed off upon them as genuine shirtings.

Let the silk manufacturers take warning: to meet falling markets with inferior goods dressed and dodged so as to simulate a better article is simply to hasten on the time of trouble and disaster. Markets have reputations as tender as that of Cæsar's wife. If such malpractices continue we shall soon be clamouring, in the interests of commercial morality and of national prosperity, for an extension of the Adulteration Act from our Food to our Clothes.

DARWINISM AND OTHER ESSAYS

Darwinism and other Essays. By John Fiske, M.A., LL.B., formerly Lecturer on Philosophy, Instructor in History, and Assistant-Librarian at Harvard University. (London: Macmillan and Co., 1879.)

TO readers of NATURE there is nothing new and little very striking in these essays, and it is only justice to Mr. Fiske to remark that the title of the first, which gives its name to the volume, claims nothing of the sort. The most interesting consideration in the four papers upon the subject is the marvellous way in which every science and line of thought, both in natural history and in human history, have entirely changed their aspect and started in a new direction since the publication of "The Origin of Species." One fourth of the book is a review of Mr. Buckle's "History of Civilisation," written and published by Mr. Fiske when he was nineteen years old: the object of reprinting which now it is hard to see. Yet it is interesting read in immediate juxtaposition with the chapters on Darwinism, for nothing could show so distinctly how high and dry the stream of knowledge has left the whole theory of a work most celebrated only twenty years ago. Buckle's book, the theorem of which was that there is a science of history, the laws of which are as uniform and invariable as those of mechanics or astronomy, if only we could discover and measure all the various forces at work, was an energetic effort in the right direction, and was gladly welcomed by many scientific men of the day. But the key to the puzzle had not then been found. Had Buckle lived in these days, when the works of Darwin, Herbert Spencer, and Sir H. Maine are familiar, he would, no doubt, have built up a far more coherent theory than he did.

In two other papers in this volume we find development working in two very different spheres, viz., in the production of a nation, in the account of "The Races of the Danube," and in the production of a catalogue, in his description of a "Librarian's Work." Had Mr. Fiske

carried out the former more in the spirit of Buckle and Darwin, it would have added greatly to the interest of the paper and to the coherency of the book. There is also a fairly contemptuous article on "Psychic" force and its manifestations, as described by those who believe in it. His "Crumb for the Symposium" is certainly a dry one; his arguments throw no light on a very dark subject; but he draws an agreeable contrast between ten disputants on the subject of a future life meeting in the sixteenth century, and adjourning to some ecclesiastical court preparatory to a final settlement at Smithfield, with their now forming a symposium for a fair discussion in *The Nineteenth Century*.

Scattered through the book are many eloquent passages of scientific teaching. There is a striking description (p. 18) of the changes the surface of the earth has undergone, which might have prompted Byron's lines on the changelessness of the ocean. One cannot but expect good teaching from a man who lays down the excellent rules and takes the high standard of both learning and teaching truth which Mr. Fiske does, in his affectionate notice of Mr. Chauncey Wright, an eminent specimen of a class of men who, though little thought of and almost unknown individually, are yet the "good belly" which absorbs and distributes all the fresh acquisitions of more active and enterprising "members" of society. And the most valuable habit of mind in such persons is the kind of scepticism recommended by Mr. Buckle, though Mr. Fiske hardly seems to comprehend the feeling, which consists in distrusting received opinions as final; not in refusing to hold any opinions at all, but in being ready to doubt as soon as any good reason is offered. A theory, like a fire, is a very good servant but a very bad master, and true scepticism consists in willingness to give up a theory as soon as facts are brought out with which it is inconsistent. Mr. Fiske praises this high quality in Darwin (p. 34), but in other passages in his book it would appear that he urged a spirit of doubting old axioms only. He seems to think it right to put full faith in a newly-formed opinion, and to "repose" upon it (p. 175). One would have thought that the severe criticisms in his larger work, on Comte's premature conclusions, would have led him to be less confident in scientific "truths," and it is curious to see the spirit that ruled Mr. Chauncey Wright praised by a man who has confidently laid down a cosmic philosophy. Still the harm is not in airing cosmic theories—there are many valuable advantages in doing that—but in clinging to them, as human weakness is only too apt to do when they are no longer consistent with latest observations.

OUR BOOK SHELF

A Ministry of Health, and other Addresses. By B. W. Richardson, M.D., F.R.S. (London: Chatto and Windus, 1879.)

THIS is a collection of addresses given by Dr. Richardson, mostly in his capacity of propagandist of sound ideas as to individual and especially national health. In the lecture which gives the title to the volume he advocates the national urgency for a responsible minister of health, not so much to obtain new sanitary laws as to enforce the multitude of existing laws on the subject, which, from the want of any central authority, are at present a dead letter. Dr. Richardson's arguments are forcible, and must be convincing to any unprejudiced mind, and we trust that ere long his recommendations will be given practical effect to. The second paper is a sympathetic and extremely interesting sketch of the life and work of William Harvey, the model physician, teacher, and public man of his time. The other lectures are: "A Homily Clerico-Medical," "Learning and Health" (in which some valuable hints as to educational methods are given), "Vitality, Individual and National," "The World of Physic," "Burial, Embalming, and Cremation," "Registration of Disease," "Ether-Drinking, and Extra-Alcoholic Intoxication."

Frozen Asia: a Sketch of Modern Siberia. By C. H. Eden. (London: S.P.C.K.)

MR. EDEN has collected in this neat little volume a good deal of valuable information concerning Siberia. The information, however, is somewhat fragmentary in its nature, and not well digested in parts, long quotations from books and journals and daily papers being indulged in. Mr. Eden, in his account of recent explorations, confines himself to a few voyages (mainly Nordenskjöld's) along the coast, ignoring all that has been done in the interior. He, we regret to see, makes use of that most vicious and misleading term, "Turanian," and actually talks of certain quite unrelated peoples as belonging to a mythical "Turanian Stock." The sooner the word is banished from ethnological terminology, the better for the progress of the science. The book, so far as it goes, contains much trustworthy information.

Jack's Education; or, How he Learnt Farming. By Prof. H. Tanner, F.C.S. (London: Chapman and Hall, 1879.)

PROF. TANNER has put together, in the form of a really readable story, a series of papers for the purpose of showing the manner in which the science classes and the Government Department of Art enable a youth to prepare himself for the Government Scholarships, and by a tolerably complete course of science instruction qualify him for learning any industrial occupation with a thoroughly intelligent mind. The instruction in science given in colleges is reviewed from the standpoint of practical requirement, and with special regard to such a course of study being rendered most valuable as a preparation for learning any commercial industry. The story is both instructive and interesting, and we recommend it to all interested in "technical" education.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Greenwich Meteorological Observations

THE notice of the recently published "Reduction of Greenwich Meteorological Observations," NATURE, vol. xx. p. 525, contains remarks which seem to show misconception in regard to some points of the work. On these the Astronomer-Royal has requested me to offer suitable explanation.

Some criticisms, p. 526, on the table of mean air-temperatures deduced from eye-observations (Table 125), terminate with the remark that the mean temperatures for Greenwich "remain still to be calculated." But it appears to be overlooked that a complete table of standard mean temperatures, daily and monthly, deduced from the photographic records for the twenty years, 1849 to 1868 (from twenty-four readings on each day), is to be found on p. 49 (Table 77). In forming the daily means, values for the few days on which no photographic value was available were derived from the eye-observations; the results thus completely represent the period 1849-1868, and will form

our standard of reference for air temperature until a further reduction of the photographs shall enable us to extend the period and so further improve them. The mean temperature of Greenwich, according to Table 77, is 49°·72.

The mean temperatures of Table 52 are also deduced from the photographs, without correction for omitted days; they serve to show the climatic variations in different years: if desired, the effect of the omitted days could be readily determined. Here the mean temperature comes out 49°·69.

The table of mean air-temperatures for the period 1847-1873, deduced from eye-observations (Table 125), to which particular attention is drawn, p. 526, is naturally of secondary importance, and really owes its introduction into the volume partly to accident. It was thought desirable in preparing for press the deductions from the photographic records, to add, in the same volume, but in a separate section, a collection of results of the observations of the earth-thermometers for the period 1847-1873, and a table showing the mean air-temperature during the same period seemed a proper accompaniment to these results. Now the photographs had been discussed only for the period 1849-1868, and, as there were already existing mean temperatures for the longer period, 1847-73, deduced from eye observations (by use of Mr. Glaisher's corrections), these temperatures were taken for comparison with the earth-thermometer results. The expression "accurate mean temperatures" (last line of extract, p. 526) was never intended to indicate that Table 125 should supersede Tables 52 and 77, but simply to explain that the air temperatures were *mean* temperatures as distinguished from the *noon* temperatures of the remaining tables of the section. Further it is indicated in a sentence not quoted, but forming portion of the paragraph from which the extract already referred to is taken, that the eye observation series was adopted for this section because photographic results were not available for the whole period. It may be here explained that employment, for reduction of the eye-observations, of the corrections for diurnal range, &c., given by the photographic records, produces values in harmony with the photographic values, and corrections so derived are now used in the reduction of eye-observations for immediate use. But Table 125, as it stood, fulfilled the object for which it was inserted, that object being rather to exhibit *variations* of temperature. No argument founded on the absolute temperatures shown by the earth-thermometers has much significance, because we are unable to test their index errors. In fact, the true value of the whole collection of tables in the earth-temperature section consists, not on their exact indication of absolute temperature, but on the information which they afford in regard to comparative changes of temperature, the retardation of temperature, and generally the propagation downwards of surface-waves of temperature.

In the last paragraph of the notice attention is directed to what is called the "somewhat rough method" adopted in reducing the barometric observations to 32°. This erroneous idea may have, perhaps, been encouraged by the circumstance that in the Introduction no mention appears to have been made of the fact that the temperature of the underground apartment in which the photographic barometer is placed is almost uniform. Considering this in connection with the construction of the apparatus, in which (as fully explained in the Introduction) the register depends on the height of the mercury in the lower tube of a syphon barometer, and is influenced by the expansion of some four inches only of the mercurial column, it will be understood that the effect of temperature (change of temperature) in a period of twenty-four hours (the extent of one sheet) is not perceptible.

In the third and fourth lines of the paragraph, on p. 526, commencing "From this table," it would seem that the word "excess" should be "defect." WILLIAM ELLIS

Royal Observatory, Greenwich, October 7

Saturn's Dusky Ring

I WRITE to call the attention of observers to the present appearance of the inner dusky ring of Saturn. Although the ring is not very open, only permitting that portion near the ends to be seen on the nights of the 9th and 11th of this month, using a portion of a large reflector sufficient only to show Enceladus clearly, it was most prominent, and not to be overlooked. It had the appearance of being covered with bright points, such as a rough dusk paper touched lightly with chalk would give; that part in front of the ball being dark, and showing as a fine dark line across, equal in width and shade to the shadow beneath, so that the narrow part of the whole ring appeared on the face of the planet as if bounded by two fine parallel dark lines. The wide and the narrow division at the ends of the ring were very plain.

Not having seen this dusky ring before, I can only go by the published accounts, but it is so much brighter than they would lead one to suppose that it is very difficult to believe that it is not changing very rapidly. The observation of one to whom the ring is familiar would settle this point. A. A. COMMON

Ealing, October 13

Suicide of the Scorpion

DOUBTS having been expressed at various times, even by learned naturalists, as to the reality of the suicide or self-destruction of the scorpion by means of its own poison, and these doubts having been again stated in NATURE, vol. xx. p. 553, by Mr. R. F. Hutchinson, of Peshawar, as the result of his own observations, I think it may be useful to give an articulate account of the phenomenon as it has been related to me by an eye-witness, which removes all possible doubt as to its occurrence in certain circumstances.

While residing many years ago during the summer months at the baths of Lucca, in Italy, in a somewhat damp locality, my informant, together with the rest of the family, was much annoyed by the frequent intrusion of small black scorpions into the house, and their being secreted among the bedclothes, in shoes, and in other articles of dress. It thus became necessary to be constantly on the watch for these troublesome creatures, and to take means for their removal and destruction. Having been informed by the natives of the place that the scorpion would destroy itself if exposed to a sudden light, my informant and her friends soon became adepts in catching the scorpions and disposing of them in the manner suggested. This consisted in confining the animal under an inverted drinking-glass or tumbler, below which a card was inserted when the capture was made, and then, waiting till dark, suddenly bringing the light of a candle near to the glass in which the animal was confined. No sooner was this done than the scorpion invariably showed signs of great excitement, running round and round the interior of the tumbler with reckless velocity for a number of times. This state having lasted for a minute or more, the animal suddenly became quiet, and turning its tail or the hinder part of its body over its back, brought its recurved sting down upon the middle of the head, and piercing it forcibly, in a few seconds became quite motionless, and, in fact, quite dead. This observation was repeated very frequently; in truth, it was adopted as the best plan of getting rid of the animals, and the young people were in the habit of handling the scorpions with impunity immediately after they were so killed, and of preserving many of them as curiosities.

In this narrative the following circumstances are worthy of attention:—(1) the effect of light in producing the excitement amounting to despair which causes the animal to commit self-destruction; (2) the suddenness of the operation of the poison, which is probably inserted by the puncture of the head into the upper cerebral ganglion; and (3) the completeness of the fatal symptoms at once induced.

I am aware that the phenomena now described have been observed by others, and they appear to have been familiarly known to the inhabitants of the district in which the animals are found. Sufficient confirmation of the facts is also to be found in the narratives of G. Biddie and "M. L." contained in NATURE, vol. xi. pp. 29, 47, and it will be observed that the circumstances leading the animal to self-destruction in these instances were somewhat similar to those narrated by my informant. It is abundantly clear, therefore, that the view taken by Mr. Hutchinson, viz., that the "popular idea regarding scorpionic suicide is a delusion based on an impossibility" is wholly untenable; and indeed, the recurved direction of the sting, which he refers to as creating the impossibility of the animal destroying itself, actually facilitates the operation of inflicting the wound. I suppose Mr. Hutchinson, arguing from the analogy of bees or wasps, imagined that the sting would be bent forwards upon the body, whereas the wound of the scorpion is invariably inflicted by a recurvation of the tail over the back of the animal. ALLEN THOMSON

London, October 11

Climatic Effects of the Present Eccentricity

I ASK for an explanation of the following difficulty:—

Dr. Croll says, in his "Climate and Time" (p. 65), that "the

temperature of a place, other things being equal, is proportional to the heat received from the sun."

His reviewer in the *Quarterly* for July last says: "The mean January temperature of England may be taken at 39° F., which is equivalent to 278° F. of absolute temperature" (meaning, above the temperature of space taken at −239° F.), "and if we calculate what would be the mean temperature of the same month when the sun was distant 97,500,000 instead of 91,000,000 of miles as it is now, we find it comes out 242° F., which is equivalent to 3° F. of our thermometer, or 29° of frost."

If we use the same method to find to what extent the present value of the eccentricity ought, even now, to affect temperatures on the earth's surface, we arrive at a result apparently so contrary to experience that I think "there must be a mistake somewhere." I ask your readers to tell me where.

Let S be the temperature of space. Choose two places in equal north and south latitude; and let U, U' be their July temperatures respectively, A, A', their January temperatures, *i.e.*, at aphelion and perihelion; e the eccentricity. Then we have, according to the principle used by Mr. Croll and his reviewer—

$$\frac{S + A'}{S + U} = \left(\frac{1 + e}{1 - e}\right)^2.$$

With the present value of the eccentricity, viz., 0·0168, this gives—

$$A' = 0·0695\, S + 1·0695\, U,$$

giving to S the usually accepted value, −239° F.

$$A' = 16·61 + 1·0695\, U.$$

$$\therefore A' - U = 16°·61 + 0·0695\, U \quad . \quad . \quad . \quad (1)$$

That is to say, the January temperature of the place in south latitude, ought to exceed the July temperature of the place in equal north latitude by more than 17° F.

In like manner we find the relation between U' and A to be—

$$U' - A = -15°·53 - 0·07\, A \quad . \quad . \quad . \quad (2)$$

That is to say, the July temperature of the place in south latitude ought to be more than 16° lower than the January temperature of the place in north latitude.

Now it may be replied that geographical and meteorological causes may completely mask these differences. The mean June temperature of the northern hemisphere is known to be higher, instead of lower, than the mean December temperature of the southern hemisphere, and it is considered that this is sufficiently accounted for by the excess of land there. If this explanation be true, the effect of the excess of land must be capable of increasing the mean temperature not only by the number of degrees by which the northern hemisphere exceeds the southern, but by this amount *plus* 17° F.

Subtracting (2) from (1)—

$$(A' - U') - (U - A) = 32°·14 + 0·07\, A + 0·069\, U.$$

This shows that, so long as A' is greater than U' and U greater than A, this difference is greater than 32°. That is, the difference between the excess of summer temperature over winter in the southern hemisphere exceeds the like excess in the same latitude north by more than 32°. Is there any indication of an excess of annual variation in anything like this extent in the southern hemisphere?

But observe the result at the equator. If the latitudes of the two places are continually diminished they will eventually be found both of them on the equator; in which case A' and A become identical, and likewise U' and U. Now the right-hand side of the equation being positive, the left-hand side must be so too. Hence $-(U - A)$, which was negative, in becoming $A' - U'$, which is positive, must pass through zero. This shows that one effect of the eccentricity is that it is not under the equator that the January and July temperatures are the same, but under some latitude north of the equator.

When the two places are both on the equator, or rather when only one place upon the equator is considered,

$$A - U = 16·07 + 0·03\,(A + U) \text{ (nearly).}$$

If we put for $\frac{1}{2}(A + U)$ the mean temperature of the equator, or 80° F., this equation gives $A - U = 21°$. F. nearly.

That is to say, the January temperature of a place on the equator ought at the present time to be about 21° F. higher than the July temperature, if the temperature of space is so low as −239° F.

The temperatures themselves would be—

$$A = 90°\tfrac{1}{2},\ U = 69°\tfrac{1}{2}.$$

I would ask, therefore, whether there is any indication of so great a difference as the above at any station on or close to the equator.

If $A - U$ is not so great as 21° F., it must be owing to causes which diminish A or increase U. The place being on the equator, would not be reached by the north-east trade-winds; moreover, in July their extension towards the equator would be least. Consequently, they would have little effect to increase U by bringing warmth from the heated continents. In a similar way the south-east trades would be at their weakest in January, and have their least effect to diminish A by bringing cold air and water from the Southern Ocean. Meteorological causes would, therefore, seem to tend rather to exaggerate than to mask the difference in question, if the observations were taken in an insular position near the equator.

I believe there is admitted to be some uncertainty about the value used for the temperature of space. Herschel's investigation in his meteorology may not be thought satisfactory. But it is remarkable that Pouillet, following quite a different method, arrived at almost the same result. At any rate the temperature which the earth would assume, were the sun extinguished, must be very low. But is it so low as −239° F.? If it were, it appears that, if the principle used be correct, those results would follow which I have suggested; and I ask whether any observations bear upon the question? It is obvious that it touches Dr. Croll's celebrated theory somewhat closely. O. FISHER

Harlton, Cambridge, October 4

Does Sargassum Vegetate in the Open Sea?

HAVING had many opportunities of observing patches of "living Sargassum in the open sea" from the deck of H.M.S. *Challenger* during her cruise in the North Atlantic in the early part of the year 1873, I venture to offer a few remarks in reply to the above inquiry of your correspondent in NATURE, vol. xx. p. 552. The track of our ship between Madeira, the Canary Islands, St. Thomas in the West Indies, Bermudas, and the Azores is almost equivalent, as a glance at the map will show, to a complete circumnavigation of the central part of the North Atlantic generally known as the Sargasso Sea. During this cruise *Sargassum bacciferum* was met with frequently so as to render the appearance of this seaweed a sight quite familiar to all on board the *Challenger*. It was first seen on March 2 in about lat. 22° 30′ N., long. 42° W., halfway between the Canaries and the West Indies. Again on March 6, lat. 21° N., long. 49° W., quantities of gulf-weed drifted past the ship. On more than one occasion large patches of Sargassum were observed extending from the vicinity of the vessel to a great distance. The gulf-weed was also encountered between St. Thomas and the Bermudas group, and was last met by us between the latter islands and the Azores on June 18, lat. 35° N., long. 53° W.

As regards the exact form and appearance of this interesting alga, I cannot do better than quote from the graphic description given by Sir C. Wyville Thomson in the pages of "The Atlantic," vol. ii. pp. 9, 10:—

"They (the patches) consist of a single layer of feathery bunches of the weed (*Sargassum bacciferum*), not matted but floating nearly free of one another, only sufficiently entangled for the mass to keep together. Each tuft has a central brown thread-like branching stem studded with round air-vesicles on short stalks, most of those near the centre dead, and coated with a beautiful netted white polyzoön. After a time vesicles so encrusted break off, and where there is much gulf-weed the sea is studded with these little separate white balls. A short way from the centre, towards the ends of the branches, the serrated willow-like leaves of the plant begin; at first brown and rigid, but becoming farther on in the branch paler, more delicate, and more active in their vitality. The young fresh leaves and air-vesicles are usually ornamented with the stalked vases of a *Campanularia*. The general colour of the mass of weed is thus olive in all its shades, but the golden olive of the young and growing branches greatly predominates. The general effect of a number of such fields and patches of weed, in abrupt and yet most harmonious contrast with the lanes of intense indigo which separate them, is very pleasing."[1] On p. 339 of the same volume we find the following remark:—"Very few of the higher algæ live even occasionally on the surface of the sea; the notable exception is the gulf-weed

[1] "The Atlantic," by Sir C. Wyville Thomson. (London: Macmillan and Co., 1877.)

(*Sargassum bacciferum*), which scatters its feathery islets over vast areas of warm, still water; and affords rest and shelter to the peculiar nomadic fauna to which I have already alluded (vol. i. p. 186, &c.)."

My colleague on board the *Challenger*, Mr. H. N. Moseley, on p. 567 of his recently-published "Notes by a Naturalist,"[1] refers to the pelagic habits of Sargassum and other sea-weeds in the following words:—

"Besides these smaller algæ (*Trichodesmium*) living in the open ocean, there are abundance of several species of larger sea-weeds which are pelagic in habit. The Gulf-weed, *Sargassum bacciferum*, of the Sargasso Sea in the Atlantic, is well known. It is brown when dried or preserved, but when living is of a very bright yellow colour, which contrasts pleasingly with the deep blue of the open Atlantic. Another sea-weed (*Fucus vesiculosus*) is to be found also living free in the Atlantic, and the Giant Kelp (*Macrocystis pirifera*), in the floating condition, ranges over a wide belt of the Southern Ocean, as proved by Sir Joseph Hooker ('Flora Antarctica,' vol. i., pp. 464-465).

"All these sea-weeds grow attached to rocks on various shores as well as free, but they all produce spores, only when attached. The pelagic varieties multiply only by simple growth and subdivision. A wide area covered with sea-weeds corresponding to the Sargasso Sea occurs in the North Pacific Ocean."

In refutation of one of the fanciful reports alluded to by your correspondent, namely, that some branches of the floating Sargassum rise two inches above water, and are thus driven along by the wind, I may add that the bunches of the Gulf-weed float at, but not upon, the sea-surface, being almost completely immersed in the water, and often entirely so. At times, when a patch of weed is seen crowning the top of a wave, the tips of the feathery bundles protrude above the water, without, however, presenting a surface large enough for the wind to act upon. Probably, owing to the action of surface-currents, an apparently endless procession of patches, large and small, may be often observed drifting past the ship, forming in the aggregate long yellow streaks or bands, which cover the sea as far as the eye can reach.

J. J. WILD

The Temple of Nodens in Lydney Park

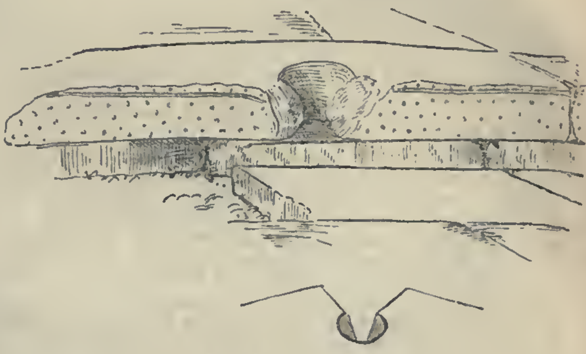
PROF. RHŶS' interesting review on Mr. King's volume in NATURE, vol. xx. p. 285, has been recalled to mind by the notice of the same quarto in Saturday's *Athenæum* (September 27); and I would remind those interested of the occurrence of a somewhat analogous relic of ancient rites in the pavement of the primæval fane on the island of Gozo; which relic was first (I believe) noticed by myself in the pages of the *Athenæum* in November, 1872. A fuller account, with diagrams of the pavement, appeared subsequently in the *Journal* of the Anthropological Institute, vol. iv. (Plate vi.) in a paper on the "Non-historic Stone Relics of the Mediterranean."

Prof. Rhŷs writes: "We have not yet done with the pavement, for in the part occupied by the dedicatory inscription, but not quite in the centre, seemingly not to cut up the names, as Mr. King thinks, there is what he describes as 'a circular opening, nine inches in diameter, surrounded by a broad red band again inclosed in two others of blue.' That some high mystery was involved in the setting of this unsightly object in so conspicuous a position, cannot admit of any doubt." He comes to the conclusion that this funnel was meant to receive libations poured to the god, and that they were drunk up by the dry soil beneath. He further compares this opening in the pavement "to the well of salt water, that famous memorial of the former presence of Poseidon in the Acropolis of Athens."

Compare this with my account of the Gozo pavement in 1872, as follows:—

"In the pavement of the inner left-hand pair of chambers at Gozo, to the right are the partially-covered remains of a large stone basin, or hollowed stone with a broad raised brim, and in the threshold of the entrance, between the two chambers, a broken holed stone, at the base of which was some coarse burnt clay, hollowed so that the stone could hold water. At Hagiar Khem these holed stones or stone rings are frequent, and may have been used for holding the pins on which the valves of heavy doors turned, or, more probably, may have served to support earthenware *amphoræ* or *cadi*, with pointed bases, as was commonly the practice amongst not only the ancient Egyptians, but also the Greeks and Romans.

"The most unaccountable feature, however, in the whole of the monuments is to be found in the central stone of the platform of the centre apse at Gozo, right opposite to the entrance of the left-hand pair of chambers. This consists in a curious *funnel-shaped*



concavity, with one side cut away to the edge of the step of the platform of which it forms part. It is sharply cut, and in tolerable preservation, and seems designed as a species of socket in which some portable pillar, pole, altar, or vase could be fitted and fixed, or unshipped and replaced, on separate occasions. The reader may suggest some more practical use for which it may have been intended."

Accordingly, I would now adopt Mr. King's suggestion that, like the terra-cotta funnel fitted into the similar orifice at Lydney, it was meant to receive the drink-offerings of blood or libations of wine poured to the "god of the deeps." Anyhow, this would add effect to the surmise that a primæval fane of huge stones (very doubtfully *Druidical*! may I suggest *Phœnician?*) had been converted into a Roman temple for the benefit of the Latin-speaking iron-workers, "*prope Sabrinum ostium*." The *Athenæum* reviewer reminds Mr. King that there is no *classical* authority that connects Druidism directly or indirectly with any stone temple or megalithic remains, adding, however: "*The dolmens of Wales are probably posterior to the withdrawal of the Romans.*" What authority can he claim for this except Mr. Fergusson's Arthurian myths from the Welsh triads in Herbert's "Cyclops Christianus." I should be glad if Prof. Rhŷs would deal with this question, and ask if he can reconcile the following theories of Fergusson in his "Rude Stone Monuments":—

1. The post-Roman dolmen-builders came "from the south, first touched in Cornwall, and thence spread northwards, settling on both sides of St. George's Channel, and leaving traces of their existence on the south and both coasts of Ireland, as well as in Wales and the west of England generally" (see p. 274).

2. The Siluri and Brigantes emigrated from Spain to the banks of the Severn 261 years before our era (p. 381).

3. "We find the Bryts beginning to use stones after having been driven from the fertile plains of the east into the fastnesses of Cumberland and Wales; so we find the Spaniards first adopting rude stone monuments after having been driven into Portugal and the Asturias" (p. 380).

4. Locqmariaker and the monuments of the River Boyne were all erected in the first four centuries after Christ (p. 370).

5. The Crozon and Carnac monuments ascribed to the Arthurian age, 380–550 A.D. (p. 375).

6. The dolmen of Confolens: "It is a dolmen pure and simple, and it was erected in the twelfth century" (p. 336).

The Phœnicians, who dealt with the tin-workers of Cornwall, must have been amongst the first navigators who explored the banks of the Severn and recognised the mineral treasures of the Forest of Dean.

S. P. OLIVER

P.S.—Since writing the above I notice that M. Carapanos and M. Foucart found certain lead plates from the ruins of Taracovista (the ancient Dodona), on which petitions similar to that of Silulanus are inscribed; for instance, one Agis consults the great Zeus on the subject of his pillows and blankets, which he has lost or had stolen from him; whilst another, a shepherd promises his gratitude to Zeus if he succeeds in rearing his sheep, &c. These tablets and bronzes found with them were exhibited at Paris last year. The great Dodonian Zeus therefore

[1] "Notes by a Naturalist on the *Challenger*," by H. N. Moseley, M.A., F.R.S. (London: Macmillan and Co., 1879.)

may have been the prototype of the Silurian *Nodons*. What is the orthography of Lydney? S. P. O.

Do Bacteria or their Germs exist in the Organs of Living Healthy Animals?

IN the August number of the *Journal für praktische Chemie*, Messrs. Nencki and Giacosa assert that bacteria and their germs exist in the organs of healthy living animals, in contradiction of Messrs. Chiene and Ewart, who took the negative side of this question in the *Journal of Anatomy and Physiology* for April, 1878. I give the chief parts and points of Nencki and Giacosa's refutation.

"Dr. Burdon Saunderson repeated Tiegel's experiments. The organ just taken from a newly-killed animal was immediately plunged into paraffin heated to 110°. As soon as the mass cooled the surface was covered with Venetian turpentine, so as to protect the specimen from infection from without by the cracking of the paraffin. Burdon Saunderson announces that when two days after, the organ at the bottom of the vessel was taken out, it was in a clotted and rather cooked condition on the outside in consequence of the heat. But the centre contained numbers of bacteria in the various stages of their existence. . . . The last-named authors (Chiene and Ewart) worked upon the conclusion that in the time between extracting the organ and plunging it into the paraffin, bacteria germs from the air fall upon it, thus causing the subsequent decomposition. This was to be guarded against by an antiseptic method. Their procedure, therefore, was as follows:—Under a continuous spray of a solution of carbolic acid, a newly killed rabbit's abdomen was opened, and the liver, spleen, kidneys, and pancreas extracted. The liver was cut into several pieces; some pieces were wrapped in gauze, soaked in a solution of carbolic acid. Others were wrapped in unprepared gauze; while others were put into jars which were raised to a great heat, and then closed up with wool, gauze, or glass covers. The same was done with the other organs. After three days, the specimens were examined, and no bacteria were found in those which had been wrapped in antiseptic gauze. . . . Messrs. Chiene and Ewart therefore conclude that if the organs are treated antiseptically after death, no bacteria or germs of them will be found; and that hence no germs of bacteria exist in the living, healthy organs. . . ." Messrs. Nencki and Giacosa thus describe an experiment which they made, in order to prove the contrary. There was a vessel containing mercury; a large glass test-tube, filled with mercury, closed with a slip of glass, and inverted in the vessel. The latter was then heated till the tube was one-third filled with mercury vapour, which must have destroyed any bacteria which could by any possibility have remained in it. The vessel was allowed to cool; the quicksilver in the tube condensed again; and when the mercury in the outer jar was at 120°, it was covered with a 5 per cent. solution of carbolic acid." Some internal organ (liver, heart, kidneys, or spleen) was then taken from a rabbit that had just been killed, and with a pair of tweezers was brought under the mouth of the tube, up which it ascended when let go. The apparatus was then kept at a temperature of 40° for several days. The results of all experiments conducted in this way were favourable to the admission that bacteria exist in the organs of living healthy animals. Already in twenty-four hours all the organs, when examined, gave out an intensely foul odour, and showed countless split fungi in different forms. . . . The beginning of putrefaction is shown by the pressing down of the mercury in the tube by the generation of gases. . . . All the vessels and instruments we employed were lifted out, immediately before use, from a carbolic acid solution. . . . Why, then, did putrefaction not set in in Messrs. Chiene and Ewart's experiments? That neither a spray of, nor transient immersion in, carbolic acid will kill the germs in the tissues, is proved by our experiment, in which the organ is passed through the solution into the mercury and up the tube. But it is a different thing when the organ is for a long time in contact with material (the antiseptic gauze) previously soaked in the solution of carbolic acid." This, Nencki and Giacosa prove by experiment. And it seems to be natural that while a brief immersion in the antiseptic solution must be amply sufficient to destroy any bacteria which might have lodged upon the organ in its transit through the atmosphere, prolonged contact with the solution must cause the inmost parts of the specimen to be permeated by the destroying poison, thus rendering the results of the subsequent examination null and void in their bearing on the question. In conclusion, Messrs. Nencki and Giacosa maintain that pathologists must accept the fact that the germs of bacteria exist in the organs of living healthy animals, and advise them to consider this in their studies of infectious diseases, as the existence of ordinary decomposition bacteria in the tissues indicates that it may be different forms of them which are the causes of various contagious maladies. E. BURKE, jun.

Subject-Indexes to Transactions of Learned Bodies

MR. GARNETT, in his paper printed in NATURE, vol. xx. p. 554, proposes to make the Index to Scientific Periodicals by cutting up two copies of the Royal Society's Catalogue and using this as the "copy" for the Index; but the thought has struck me that if the "copy" of the Royal Society's Catalogue is still in existence there is the material ready to hand for commencing work at once. I believe the Index might be done this way by any one who had access to the chief periodicals; but the title of a paper is often so very deceptive that without frequent reference to the papers themselves I am afraid we should get even worse mistakes than the one mentioned by Mr. Garnett. Now that the last volume of the Catalogue is out it is sincerely to be hoped that the Council of the Royal Society will take this "Subject-Index" into consideration. JAS. B. BAILEY

October 10

Change of Colour in Frogs

IT is certainly a common opinion in this part of the country that when frogs become of a bright yellow colour fine weather may be expected. The brightness of colour can scarcely be due to the presence of sunlight, for frogs of a bright yellow may frequently be found in cellars, wells, and other dark places. Throughout the past summer and up to the present time, I have noticed that the frogs in this neighbourhood have been of an extraordinarily brilliant yellow tint. Again and again have I heard the country people, working in the hay or corn fields, under the unbroken canopy of cloud, remark—"We must be going to have fine weather now, for look at the colour of the frogs." These forecasts proved the reverse of successful.

W. CLEMENT LEY

Ashby Parva, Lutterworth, October 10

AT the commencement of "the rains" (say, beginning of June), in the island of Bombay, after the first showers, when a little water lodges in the depressions of the old-quarry tanks, the frogs issue from the crevices of the trap-rock to spawn, when the *males* (some of which are 18 inches in length from tip of toe to end of digit) assume a bright mustard-yellow colour, while the females remain brown as usual; and this change of colour takes place so rapidly, and the frogs are so numerous, that, with the falling of the showers, the bottom of the quarry becomes suddenly yellow. I never saw a frog so coloured at any other time, and I witnessed the fact above mentioned for at least two successive seasons in the same old quarry. H. J. CARTER

Devon, October 13

Intellect in Brutes

THE case of the Norwegian dog, Nero, mentioned by Mr. Horsfall in NATURE, vol. xx. p. 505, is certainly an admirable example of abstract reasoning. Here the dog thought as any man would have thought how, where, and when to catch the railway train suited to his purpose. It has reminded me that, when I was in Malta a few years ago, a fine Newfoundland dog (if I remember correctly) used to accompany Miss Hallett in her ride from Sliema to Valetta on a visit to her grandfather in Strada Forni. The ride is about four miles round the head of the harbour. On one occasion she observed that the dog had ceased to follow her, and concluded that, owing to the heat or some other cause, it had returned home. Her surprise was considerable on arriving in Strada Forni, for there she found the dog waiting for her at her grandfather's door. The explanation is, as was subsequently discovered by a frequent repetition of the same thoughtful dodge: the dog had gone to the ferry, waited there until passengers stepped into the boat, got in himself, was ferried across the harbour, and in this way was saved a long and, it may be, a hot and a dusty run. So far as I can remember, the animal had no previous experience of this short

mode of transit between Sliema and Valetta, except that he had *observed* people performing the journey by that route.

One of your correspondents some time ago gave as an instance of sagacity the case of a monkey returning to him a nut for the obvious purpose of having it cracked. It recalled to me that, several years since, I gave a nut to a monkey in the Zoological Gardens, London, whereupon the said monkey, having put the nut into his mouth and moved his jaws about with a sort of theatrical effect indicative of the hardness of the shell, returned it to me, as any child might have done under similar circumstances, with the evident object of getting me to crack it. I declined, and, at the same time, I gave back the nut. The monkey descended to the ground, laid the nut down, picked up a stone, and at once cracked it for himself, showing an intelligent idea of resources, that as my teeth were not available as a substitute for his, he could utilise a stone for a hammer.

Château de St. Léger, Darnétal, Seine Inférieure, October 7

Butterfly Swarms

INCLOSED is a specimen of butterfly which, about the middle of December, 1878, flew past my bungalow in crowds, all making for north-west, and going down-hill. In about four weeks afterwards, that is, well into January, 1879, the same butterfly began to return, this time flying to south-east, and uphill. Starting from the bungalow, I rode four miles to northwest, and went about 1,000 feet down-hill, and found the butterfles still ascending. They came from beyond a hill about 300 feet higher than the bungalow, and they went back over the same range.

On both occasions the temperature stood at about 80° F. in the shade, the winds moderate and variable, and as often against as in favour of the flight, which, on its going and coming, lasted for two to three days both ways.

On the return journey I found the butterflies settled in "swarms" on damp, sandy spots near ravines, and so thickly settled that with one sweep of a circular butterfly net fifteen inches in diameter I caught about 150.

M. B.

Hill Country of Ceylon, 3,000 feet above Sea-level, September 14

[The butterfly is one of the *Pieridæ*, and in all probability is identical with *Appias albina*, Boisduval. The habit of settling in swarms on damp spots is common to many butterflies, and even to several of the few species that occur in Britain.—ED.]

The Hunting Spider

THIS arachnid is very common out here, a very tiger amongst insects, and very interesting to watch. Its poison must be intensely virulent. If two are placed together under a finger bowl, and one happens to be the smaller, a very little manœuvring soon brings him within the instantaneously fatal grip of the larger animal; but if of equal size, a most interesting series of watchful movements and counter movements commences, each anxious to secure the first and fatal bite. Leap after leap is parried, advance of one is accompanied by a wide awake backward retreat of the other, and so on for a long time. When *the* fatal spring is made, the victim is at once *hors de combat*, and the conqueror carries it off rejoicingly. I once gave a spider a blue-bottle fly, and then learned for the first time that these insects were viviparous, for the fly in its death throes protruded a heap of active little maggots which soon died from want of a proper nidus in which to develop. On another occasion I found a hunting spider on a looking glass, and as from its movements it was evidently after game, I drew near quietly to watch. To my surprise and amusement I found that the spider was *stalking its own reflection*, and its cautious movements on tip toe, looking downwards, opened up to me a wide field of thought. What feeling was at work in that small breast? Was it the natural instinct after prey, or the burnings of jealousy in the apparent presence of a rival, or pleasure in scrutinising its own charms, now for the first time exhibited to it? If the latter, then the hunting spider is, I fancy, the lowest animal in the scale, which has been deceived or flattered by a looking glass.

Dogs, monkeys, and cats, are easily imposed on by a glass, and, as the first thing a monkey does on seeing a mirror, is to pass its hand round to the other monkey, you can soon originate a fight by grasping the hand behind the glass; and then hastily dropping it, watch the amazement of Jacko at the sudden and mysterious disappearance of his rival.

Peshawar

H. F. HUTCHINSON

GEOGRAPHICAL NOTES

ON Saturday evening the Berlin Geographical Society, presided over by Dr. Nachtigal, celebrated the birthday anniversary of Carl Ritter, the famous German geographer—a ceremony which had been postponed from August. Ritter himself founded this society in 1828, and presided over it till 1860. "Those days," said Dr. Nachtigal, in opening the proceedings, "on which their intellectual princes are presented to the nations are landmarks of their life and development, and to honour them is a duty of honour." The University, the Army, and the other kindred societies throughout Germany, were all largely represented, and handsome subscriptions were announced for a memorial to the hero of the evening.

AMONGST the resolutions passed at the Brussels International Congress for Commercial Geography we point out the following:—1. The Congress is of opinion that, in the interest of all nations it is desirable that one or more lines of railway should connect the coasts of Afric with its interior. 2. Complete freedom of trade should reign there. 3. In the expectation of a complete abolition of custom-houses, it is desirable that as many commercial treaties as possible should be concluded. It is particularly necessary that a treaty of this kind should be preliminarily entered into between Belgium and Holland. 4. The Congress expresses the wish that everywhere instruction in history should be separate from that in geography. The Congress expressed some further wishes which related to an expedition for discovering the shortest route from Mandalay to Mekong; the speedy execution of the Panama Canal project, the rendering safe of the commercial routes leading to Inner Africa, the furtherance of free trade, the amelioration of the system of representation of countries by consuls, the commercial route from Tong King to the south-west of China, the introduction of the same meridian for all countries, the construction of railways on the Balkan peninsula and in Asia Minor, the introduction of a uniform system of measures, weights, and moneys for all civilised peoples, the abolition of slavery in countries where it continues to be officially countenanced. Next year's congress will take place at Lisbon.

AN International Geographical Congress will be held at Nancy in August, 1880.

THE International Congress of Americanists was opened at Brussels on September 23. The King of the Belgians and many persons of rank were present.

THE boundary between British Guiana and Venezuela is a very vexed question, and in consequence of Mr. Boddam-Whetham having included in his recent work some notes on it from a Venezuelan source, Mr. E. F. im Thurn, a well-known authority on matters relating to British Guiana, has gone carefully into the matter. He has just embodied the results of his investigations in a little *brochure*, which contains a good deal of geographical information. Mr. im Thurn regards the following as the best settlement of the question. The mouth of the Morooca should be taken as the northernmost point of our colony, and from there to the old Dutch post on the Cuyani, the boundary should be as in Cordazzi's map. Thence it should be carried to the nearest point of the Mazaruni, and then up the course of that river to the junction of the River Cako, and along the latter river to Mt. Roraima. From that central and well-marked point, southward to the source of the Corentyne, and then northward along the course of the river, it should follow the line laid down in Sir R. Schomburgk's map.

THE special service officers, whose departure for South Africa was alluded to in NATURE, vol. xx. p. 64, have evidently done good work from a geographical point of view, for in his despatch, written from Ulundi on September 3, Sir Garnet Wolseley, in reporting the conclusion of the war, states that he has been able to extend our topographical knowledge of Zululand, and by actual survey, as well as by reconnaissances, to lay down on paper with very tolerable accuracy its rivers, mountains, &c.

THE St. Petersburg correspondent of the *Daily News* telegraphs that after the departure for England of the seven steamers which failed to get through the Kara Sea, the steamship *Louisa*, with a Russian charter, succeeded in finding a passage, and arrived at Yeniseisk, discharged her cargo, and loaded 20,000 poods of wheat for Europe. The *Golos* recommends the establishment of a meteorological station at the extremity of the Island of Waigatz, between the two gulfs, to be connected by telegraph with the other parts of the Empire and Europe.

ACCORDING to the *Colonies and India*, Mr. Alex. Forrest, in his journey across North-west Australia, from De Grey River to Beagle Bay, found large tracts of rich land along nearly the whole coast and within easy reach of the sea. From Beagle Bay he went to the western shore of King's Sound, and after passing up the Fitzroy River, returned along the eastern boundary of West Australia. He reports well-watered and grass country near Beagle Bay, though it is rather densely wooded with the cajeput, red and white gum, &c. No rivers of any size were discovered, and the country was almost entirely level. As regards natural productions, Mr. Forrest reports the pearl-shell beds to be unlimited in extent. The soil is generally a sandy loam; in some parts there are a few ironstone hills, and in others limestone is found, but nowhere are there any indications of gold.

MR. ORVILLE A. DERBY, Director of Geology in the National Museum of Brazil, we learn from *Science News*, was at last accounts about starting on an exploring expedition in the interior of the empire. He goes in company with a party of engineers who are to make surveys for a railroad route. The chief of this party is Mr. Roberts, an American. They will first ascend the river São Francisco to the Falls, which are 168 miles from the sea. They carry with them a steam launch, by means of which they expect to navigate the river above the Falls. Mr. Derby expects to leave the engineers after their work is finished, and to cross the province of Minas Geraes, celebrated for its product of gold, and he will make the geology of that region a special study. The distance to be gone over is not less than 600 or 700 miles, and will probably be much more in the detours of travel. A very hasty geological survey was made of the country in 1866 by J. A. Allen, the ornithologist, O. H. St. John, geologist, and Thomas Ward; they were then members of the famous Agassiz expedition. They began in the upper waters of the river and worked downward toward the Falls. The late Prof. Hartt explored below the Falls, to the mouth of the river. The work undertaken by Mr. Derby is in an important and very extensive field, about which very little is definitely known.

THE American expedition, gone out in search of the remains of Sir John Franklin, which landed at the northern shore of Hudson's Bay, in the vicinity of Depots Land, on August 9, 1878, continued its journey to King Williams Land in sledges, on April 1, 1879.

THE German geographers, Drs. Greef and Gasser, have arrived at Lisbon on their way to Africa. A scientific task has been confided to them, and they will begin their labours with the study of the zoology of the West African Islands.

NEWS just arrived from Pekin states that the Hungarian traveller, Count Szechenyi and his companions have started on the journey to Tibet, under protection of Chinese officials, and with an escort of thirty soldiers. They intend to visit Sining, Shen-Chung-Chia, and Tsaidam, and then to proceed on the great northern Kukunor road to H'Lassa, which is situated some 700 miles beyond Tsaidam.

EARLY in the present year the Rev. C. R. Fairey made a most remarkable missionary journey, travelling alone for some 300 miles along the dangerous north and east coasts of Tasmania. The journey was entirely performed in a canoe 12 feet long, 28 inches beam, and 12 inches in depth. Mr. Fairey now proposes to make a voyage on the Murrumbidgee and Murray Rivers in Australia.

AFTER the pattern of European Alpine Clubs a Himalaya Club is stated to have been formed in India with a view of attempting to ascend the highest peaks of that gigantic mountain chain.

UNDER the title of "La Cimbébasie" *Les Missions Catholiques* publishes some interesting geographical notes on a tract of country in Western Africa, extending on the seaboard from the mouth of the River Cunene to that of the Orange River. On the north the boundary of this region, which has lately been constituted a separate ecclesiastical district by the Holy See, marches with that of the Portuguese colony of Angola in the direction of the Mano Mountains, and then follows the right banks of the Casai and the Lotenbua as far as Lake Dilolo. On the east it runs along the Liba to the point where the Chobé (the Cuando of Major Serpa Pinto) falls into the Zambesi, and finally follows the eastern frontier of the Bechuanas from Lake Makarikari to the Rivers Vaal and Orange. In this region are included Damara-land on the north-west, Namaqua-land on the south, the tribes of the Kalahari Desert on the east, and on the north Ovampo-land, &c. These notes, which are drawn up by Père Charles Duparquet and are illustrated by a map, are the more worthy of attention, as the greater part of this large tract of country has recently been placed under the British Protectorate.

SIR GEORGE ELLIOT, M.P. for North Durham, has signified his intention to dedicate a piece of land on his estate, West Cliff, Whitby, to the public, and erect thereon a monument to Capt. Cook, who spent several years of his early life at the fishing village of Staithes, a few miles to the north of the port of Whitby. In later years he sailed from the harbour of Whitby, and it is an historical fact that in undertaking his adventurous voyages round the world he preferred the vessels which were built at Whitby by Whitby men.

MESSRS. SAMPSON LOW AND CO. are to publish Dr. Holub's Narrative of his important explorations in South Africa. They have also in the press Signor D'Albertis' Narrative of his Explorations in New Guinea; it will contain many illustrations in ethnography and natural history.

THE last *Zeitschrift* of the Berlin Geographical Society contains detailed narratives by Dr. Hildebrandt of his important journey from Mombassa to Kitur, and by Dr. Hirschfeld of a journey he made in South-West Asia Minor. The *Verhandlungen* contains a valuable description of the Galapagos Islands, by Dr. Theodor Wolf, and a series of measurements of elevations in Ecuador, by the same, both from the Spanish of W. Reiss.

FROM the American Geographical Society we have received the annual address of the president, Dr. C. P. Daly, being an elaborate and valuable paper on the Early History of Cartography, or, "Maps and Map-Making before the time of Mercator." The paper is profusely illustrated with specimens of old maps, and must have involved a great amount of research. The last *Bulletin* of the Society (No. 5 of 1878) contains a long account of a journey along the west coast of South America, from

Panama to Valparaiso, by Mr. James Douglas, and an account of a visit to the "Wonderful Rivers of Cambodia," by Mr. Frank Vincent.

DR. CREVAUX, the explorer of French Guiana, is not yet, it seems, coming home, but will attempt to reach the Andes by the Iça or Putumayo, exploring that water-system as he has already done the Marori, Ozapok, Yary, and Para.

OUR ASTRONOMICAL COLUMN

BIELA'S COMET.—Even if the earth should encounter an unusual number of meteors on arriving at the descending-node of Biela's comet next month, as some have anticipated, the display is likely to be masked to a considerable extent by overpowering moonlight. The earth will reach the node (so far as we can judge of its actual position) on November 27, and the moon will be full on the following day. Remembering that the meteors of 1872 were not generally remarkable for brightness, though there were some notable exceptions, should there be a return of the shower, a large proportion may escape notice. No doubt, however, a strict watch will be maintained during the last week in November. We are not able to judge how near we may be to the meteoric mass which the earth met on November 27, 1872; it would arrive at perihelion at the end of December in that year, but we do not know the exact period in which it was revolving.

It is worthy of note that the effect of the differences of mean anomalies and mean motions when the two nuclei of the comet were last observed in 1852, would in 1879 occasion a difference in the times of perihelion passage to the extent of nearly 3½ days, and the mutual distance of the nuclei would be increased to 0·075 of the earth's mean distance from the sun, or nearly 7,000,000 miles.

Between the year 1772, when the comet was first observed, and 1852, when the last observations were obtained, the node had retrograded upwards of 11°, the perturbation being chiefly caused by the planet Jupiter in 1794, 1831, and 1842.

When we consider the conditions under which Biela's comet appeared in 1805, we are struck with the favourable opportunity which the repetition of such a case may afford for a precise determination of the solar parallax. On the evening of December 8 in that year the comet at transit at Greenwich was distant from the earth less than 0·038, and its horizontal parallax was upwards of *four minutes;* at this time, with a declination of near 24° south, it was rapidly descending below the horizon in Europe, still it was well observable, and of course would have been in a very good position for observation at the Cape of Good Hope. Its appearance also was favourable for accurate observations, which is more than can be said of all comets that have approached near to the earth. Olbers mentions that on this evening when he was observing with Bessel, the nucleus was very small and defined like a planet, and Gauss at the same time compares it to a star of the third or fourth magnitude. There has been no such opportunity since the Cape Observatory was established.

THE GALLERIES OF THE CUTTING ANTS OF TEXAS

MR. McCOOK, the devoted student of insects, has in preparation a memoir, which will be looked for with the intensest interest, resulting from his prolonged investigations into the life-history of the cutting or "parasol" ants of Texas (*Atta fervens*), bidding fair to rival his work upon the agricultural ants.

First, let us take with Mr. McCook a brief view of a denuded surface on a high grassy prairie, covered with a number of small moundlets of fresh earth-pellets, yet without a sign of life, and looking entirely abandoned; over its surface were seen little heaps of dry twigs and pieces of leaves. But towards evening, hosts of ants hurried out, and formed two long double columns to the top of an overhanging live-oak. The ants in the descending columns all carried above their heads portions of green leaves, whence they derive their popular name of "parasol" ants. The closing of the gates in the morning came to pass thus:—Bits of dry twigs and leaves of various lengths are carried into the gallery, filling it up from half an inch to an inch and a half below the surface; often the galleries slant inwards, even to 45°; or divide soon. The larger "castes" carry in the refuse; as the hole closes the smaller castes appear. The "minims," in small squads, fill in all interstices with minute grains of sand, and finally the last steals in behind some bit of leaf, and the establishment is closed. The reverse takes place, when outside work is resumed in the evening. When the larger forms get out they at first carry away and drop their burdens, and little seems to be accomplished for a long time. But in a marvellous way there occurs a final rush, by which the gate is opened. The bigger pieces of twigs are evidently regarded as special treasures, and were seen used on several successive days. The use of the smallest castes is thus found; some remain at only one-sixteenth of an inch long, while the fertile female attains nearly an inch, and the male is three-fourths of an inch long. The interior of the formicary is composed of caverns or pockets communicating with the surface and with each other by tubular galleries. The chambers contained masses of very delicate leaf-paper wrought into rude combs. Some masses were hemispheres in shape, others were arranged in columns two and a half inches high, in contact, along the floor of the chambers, whose dimensions might be nearly three feet by one foot, and eight inches high. Some hung from tree-roots which passed through the chamber. All this material was composed of the fibre of leaves reduced to this form within the nest. In each portion of ant-comb the cells were nearly hexagonal, but very varied in size, some being half an inch in diameter, but most of them as minute as one-eighth of an inch. Large circular openings ran into the heart of the mass. Ants of the small castes were very numerous in these cells. The material of the comb was very fragile and perishable. It is supposed by Mr. McCook that the ants feed upon the juices of the leaves, but this waits further confirmation. Some of these chambers are even of very large dimensions; one of the size of a flour-barrel was seen, being the main cavity of a formicary, in which were found very many winged males and females and larvæ. This was situated 669 feet from a tree that stood in the front yard of a house, which these ants had stripped. Mr. McCook took a plan of the underground way traversed by the ants to reach this point; the course varied very little from a straight line; two branches had been made to a peach orchard 120 feet distant. Only the small forms appear to take part in the digging, while the larger assist in opening the gates, make the excursions, and do the leaf cutting. The least forms, or minims, assist in opening and closing doors, and taking charge of larvæ. The minims are quite ferocious in attack, and gallantly support the large-headed soldiers. The process of leaf-cutting has been so successfully observed by Mr. McCook, that it is quite deserving of further notice, which we hope soon to give.

G. T. BETTANY

ROUTES TO CHINA *viâ* ASAM

THE possibility of connecting India with China by a tolerably direct and easy trade route overland is a question of increasing interest to us all, in India and England. Not only would such a route benefit the large valley of Asam, by causing an influx of labour more or

less useful for the growth and manufacture of tea, and convert it from a *cul-de-sac* into a great highway. But the spectacle would be removed of two large and populous empires touching each other, and in harmony, yet having no direct intercourse.

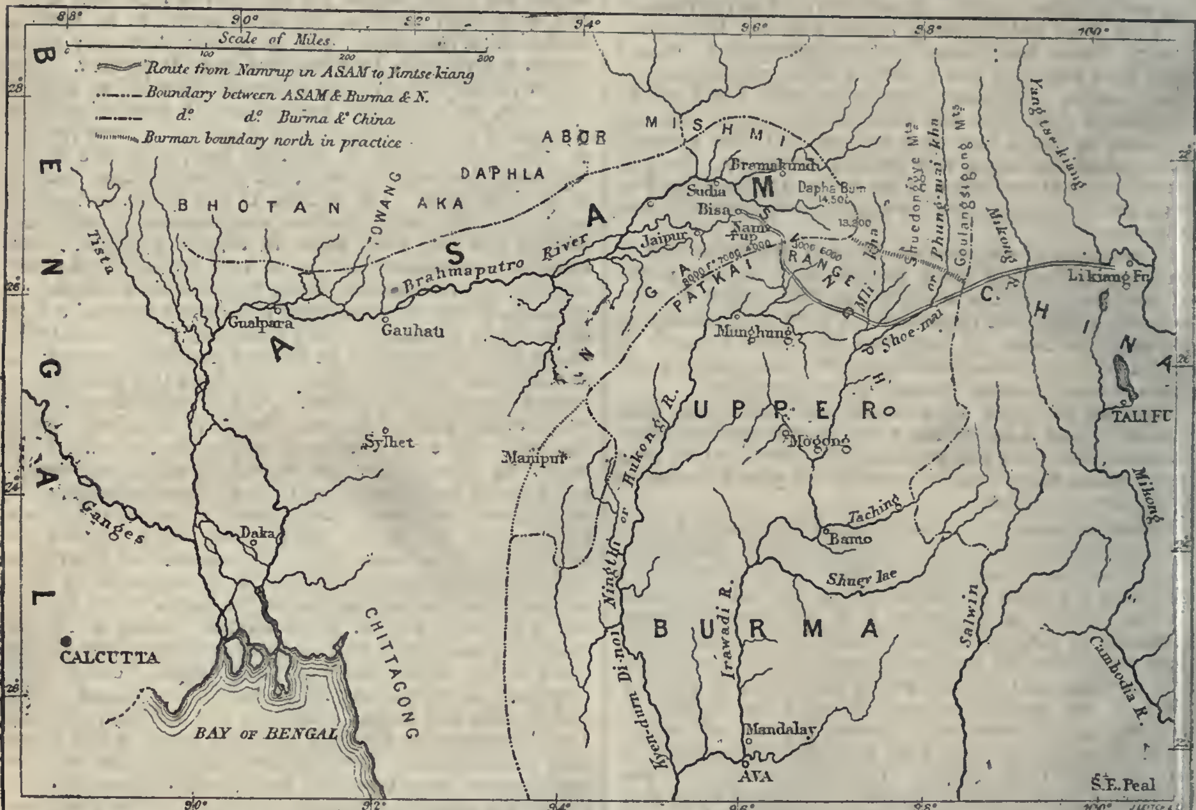
In past times this subject received careful attention from those who were in a position to judge of the relative values of the various routes, and whether *viâ* Kamaun, Nipal, Sikim, Bhutan, or the Mishmi Hills the elevations were found to range from 10,000 to 18,000 feet, often at several points on each line, and there has been an almost unanimous agreement that the route from Asam *viâ* Patkai and Hukong Valley presents the least difficulty.

Pemberton, in his report on the north-eastern frontier in 1835, after a survey of Munipúr, Passage through the Naga Hills and knowledge of the Bhutan frontier, unhesitatingly reports it as the best route "presenting no serious obstacles."

The late General Francis Jenkins (Governor-General's agent in Asam from 1834 to 1868) was well acquainted with the various routes, and says :—"By this pass is—to the best of my information—the only practicable line throughout the encircling mountain ranges from Asam and India into Burmese territory, and thence to China."

Lieut. Charlton also, who had experience on this question, says (*Journal A.S.B.*, 1835):—"What a pity there is no means of communication between Sadia and Yunan, a good land road, and there are no natural obstacles of any consequence to prevent it, would afford an outlet for British merchandise into the very heart of China."

In 1868 and also in 1869 Mr. H. L. Jenkins crossed Patkai near the site of the old route, and demonstrated that the only obstacles of any note were of a political, and not a physical nature (*Proceedings, A.S. Bengal*, July, 1870, p. 230). In January last, 1879, the Chief Commissioner of Asam kindly permitted me to cross the Patkai and ascer-



MAP SHEWING THE PROPOSED ROUTE ACROSS PATKAI TO CHINA.

tain relative and actual elevations, and briefly I may say that the extreme altitude of the track where I crossed the range is 3,445 feet above the sea, and 2,734 feet above the level of the Asam valley, the descent on the Burma side being about 1,000 or 1,200 feet only, the passage from the river levels of one side to the other being always done in one day, or one and a half if herds of cattle are taken; but it is noteworthy that the range is much lower at a short distance to the east, where it is easily seen that passes exist at 2,000 feet or less, where the old track is reputed to have been, by which the Ahoms and the Burmese army entered. The whole range is covered by a dense tree jungle, and any one acquainted with the sturdy hillmen who use this track will understand that the present route is selected simply because it presents an easy passage. The trouble of climbing a few hundred feet more or less is of little consequence to these hardy mountaineers. It is also near some villages where provisions are procurable, the country east being absolutely uninhabited.

After crossing Patkai I descended to the Nongyang Lake, a sheet of water about 1,800 by 1,000 yards, lying in an open flat grassy valley, about 10 miles long by 2 or 3 broad. As I had taken a *Rob Roy* canoe with me, I was able to get out on the lake and had a good view of the range; the lake and valley level stands from 1,500 to 2,000 feet above that of Asam. On returning, my party crossed from the Nongyang Lake on the Burmese side to the river Nunki on the Asam side, in about seven hours of actual travel.

Hitherto the great obstacle to any route this way was thought to be difficulty of crossing Patkai; it was considered an impassable barrier, even by those in favour of a joint route from Asam and Upper Burma. But it is now clear that this barrier does not exist, and that an

easy and low route is possible. Thus the first step in a good and easy trade route out of India is secured, and secured here alone.

From Nongyang the usual route for traders is *viâ* Namyung, Songphú village in a level plain of same name, thence *viâ* the Turong villages and rolling slopes of the upper part of the Dinoi valley and the low Kako hills dividing it from the Irawadi. On crossing this latter two routes are available, one up the Shoemai Kha and Sittang flat country, the other more east, turning the southern extremity of the Goulang si gong range, that coming down from the north divides Burma from China. Such a route would also pass round the heads of the Taeping, Shueylí, and Salwín valleys, and leave but one large stream, the Mikong, to cross ere reaching the Yangtse Kiang, at a point near Li kiang fu, navigable at all seasons—the main artery of China. The total distance of such a route from the plains of Asam at the Namphuk to the Yangtse I estimate at 300 miles to 350, including windings, and to clear out a serviceable bridle path or fair weather road on this I estimate would cost but 10,000*l*. The present path for long distances is a mere jungle track often obstructed by fallen trees; small deep gullies necessitate long *détours*. Were some of the jungle removed and fallen trees, a few strong logs felled over the little streams would make a good commencement.

I need not say much regarding the advantages of such a route, if available. For political reasons it was once thought desirable to discourage direct intercourse between India and China; but that day has departed. England is now one of the three great Asiatic powers, and the time has arrived when we must not only examine our passes west and east, but cultivate as far as possible a profitable and peaceful intercourse with China. The state of Upper Burma (once a Chinese province) simply renders this question urgent. At a time also when Australia and America are invaded by such hordes of cheap labourers, labour paying heavily for its own transport to distant and overstocked markets, we see Asam—close to the labour source—suffering from a want of it, and planters paying Rs. 80 and Rs. 100 per head ere they can employ labour of a very inferior stamp.

S. E. PEAL

KARL FRIEDRICH MOHR

BY the death of Dr. Mohr, of Bonn, which is just announced, the science of chemistry has lost a worker whose labours have extended over nearly half a century, and have led to great and valuable results.

Dr. Karl Friedrich Mohr was born at Coblenz in November, 1806. His earliest work was devoted to the continuation of the Pharmacopœia, established by Geiger. The work by which he will be best remembered is the "Lehrbuch der chemisch-analytische Titrirmethode," which appeared in 1855 and 1856, the second, and considerably enlarged edition, appearing in 1862. His published papers, which are very numerous, arrange themselves in two classes mainly, those devoted to meteorology and those having a bearing on volumetric analysis. Ground-ice, the earliest information about ozone, St. Elmo's fire are among the subjects of his earliest, and among his later the lower ends of lightning conductors, hail and rain, and confirmation of his theory of the formation of hail. The other more numerous class of papers on analysis extend over nearly fifty years. His examination of the method of separating copper and silver appeared in Liebig's *Annalen der Chemie* in 1832, to be followed by others on the condensation of chlorine, on Marsh's method, preparation of barium hydrate, the reduction of silver chloride, the action of the air on arsenides, and thirty years later on the value of indirect analysis, on nitrate determinations, the estimation of the different oxides of manganese, analysis without the use of weights, examination of a method of determining the specific gravity of liquids with a watch, phosphoric acid determinations, &c.

About ten years ago he published his "Allgemeine Theorie der Bewegung und Kraft," and shortly afterwards "Mechanische Theorie der chemischen Affinität."

About four years ago he sent to Liebig's *Annalen der Chemie* a curious paper on the nature and mode of origin of meteorites. He finds that all the silicates present in meteorites contain a little water, and when heated strongly or fused have a decreased specific gravity; that some meteorites contain organic compounds like certain terrestrial carbon compounds, but that meteoric iron contains no combined carbon.

THE INTERNATIONAL ASTRONOMICAL SOCIETY

THE eighth Annual Meeting of this Association was held at Berlin on September 5 to 8. The sixth and seventh meetings of the Society were held at Leyden (1875) and at Stockholm (1877). At the latter place Berlin was selected for the next general meeting, to be held in the present year. This city being more centrally situated for the greater part of the members than Leyden or Stockholm, it was expected that a rather large proportion of the Fellows of the Society would meet there; and so it has proved. There were present the following sixty-one astronomers, mechanicians, and opticians:—Abbe (Jena), Auwers (Berlin), Baeker (Nauen), de Ball (Gotha), H. G. van de Sande Bakhuyzen (Leyden), Bamberg (Berlin), Bansa (Frankfort), Becker (Berlin), Behrmann (Elsfleth), Bergmann (Berlin), Boguslawski (Berlin), Bruhns (Leipzig), Bruns (Berlin), Denker (Hamburg), Drechsler (Dresden), Elkin (New Orleans), Engelmann (Leipzig), Förster (Berlin), Franz (Königsberg), Friesach (Graz), Fuess (Berlin), Galle (Breslau), Gyldèn (Stockholm), Hasselberg (Pulkowa), Huggins (London), Kempf (Potsdam), v. Knorre (Berlin), Kreutz (Bonn), Krüger (Gotha), Küstner (Strassburg), Lehmann (Berlin), Lehman-Filhès (Berlin), Lohse (Potsdam), Maywald (Berlin), Merz (Munich), Möller (Lund), Müller (Potsdam), Neumeyer (Hamburg), Oppenheim (Berlin), Oudemans (Utrecht), Palisa (Pola), Pechüle (Copenhagen), v. Plaenckner (Gotha), Pihl (Christiania), Reichel (Berlin), O. Repsold (Hamburg), Romberg (Pulkowa), Rosèn (Stockholm), Rümker (Hamburg), Safarik (Prag), Schönfeld (Bonn), Spörer (Potsdam), Tiede (Berlin), Tiele (Copenhagen), Tietjen (Berlin), Valentiner (Mannheim), Vogel (Potsdam), Wanschaffe (Berlin), Winkler (Leipzig), Winnecke (Strassburg), Wittstein (Leipzig). Hence, besides forty-six Germans, there were present three Fellows from Austria, three from Sweden, two from Holland, two from Denmark, two from Russia, and one each from America, England, and Norway.

The Council, composed of Prof. Krüger, President, Prof. Förster, Prof. Gyldèn, Prof. van de Sande Bakhuyzen, Vice-presidents; Prof. Bruhns, Librarian, Director Auerbach, Treasurer; Secretaries, Professors Schönfeld and Winnecke, met on September 1, to consider the matters to be submitted to the meeting.

The day before the opening of the general meeting there was unveiled at the Berlin Observatory, in the presence of Encke's son and daughter, surrounded by many distinguished guests, the bust of the distinguished astronomer, who founded the new observatory at Berlin, and rendered it famous by incessant labour. The bust was made by the celebrated artist, Afinger. Prof. Förster, to whose exertions this acknowledgment of his predecessor is due, recalled to the assembled guests in spirited words the great astronomer's principal merits.

On September 5 the general meeting was opened at ten o'clock in the morning by Prof. Krüger, in the lecture hall of the Royal Academy of Sciences. The Minister for Public Instruction, Herr von Puttkammer, welcomed

the assembly in the name of the Prussian Government, and said that he hoped the new arrangements at the Royal Observatory in Berlin, and the newly-finished Astro-Physical Observatory at Potsdam would be objects worthy of the attention of foreign astronomers.

The President, after having thanked the Minister for Public Instruction, gave a summary of the number of Fellows of the Society. At Stockholm the Society had 258 Fellows; nine of these died, one left the Society, and thirty-five new Members were provisionally admitted by the Council, the number of Fellows being therefore at present 283. It is well understood that by the bye-laws of the Society there are no Associates or Honorary Members. Prof. Krüger then read an historical account, composed by the Council, of those transactions which induced Herr Struve, Director of the Imperial Observatory at Pulkowa, to resign, last year, the office of president. Then the Reports on the business during 1877-79 were read.

The treasurer (Herr Auerbach) not being able to be present at the meeting, Prof. Bruhns read his report on the expenses and the income of the Society. Besides the stock of the various publications, the *Vierteljahrsschrift* and some astronomical instruments, the Society has invested about 40,000 marks.

The librarian (Prof. Bruhns) gave a summary of books received, and stated that a catalogue of all the books had been prepared, and that it was passing through the press.

The secretary (Prof. Winnecke) reported on the publications. There have been printed and distributed to the Fellows since the Stockholm meeting, nine Hefte of the *Vierteljahrsschrift*, viz., vol. xii. Heft 4, vol. xiii. and vol. xiv. Hefte 1-3; he mentioned that it had been tried to add to the biographical notices on deceased astronomers their portraits in photography. Of the quarto publications there had just appeared:—

No. xiv. — "Fundamental-Catalog für die Zonenbeobachtungen am nördlichen Himmel. Herausgegeben im Auftrage der Zonencommission der Astron. Gesellschaft von A. Auwers."

No. xv.—E. Hartwig, "Untersuchungen über die Durchmesser der Planeten Venus und Mars nach Heliometermessungen auf der provisorischen Universitätsternwarte zu Strassburg, mit Hinzuziehung der anderweitigen vorhandenen Mikrometerbeobachtungen."

The "Ephemeriden der Fundamentalsterne für die Zonenbeobachtungen" for the year 1880, published by the *Redaction* of the *Berliner Jahrbuch*, in co-operation with the Society, has just been issued. Further, two small volumes have been printed for private circulation, the one containing the Minutes of the Council Meetings, the other giving extracts of the *Transactions* of the Council by letter.

The reading of the reports was interrupted by Prof. Förster inviting the members to visit, in the afternoon, the Royal Observatory. He gave a lucid exposition of the arrangements of the newly reconstructed observing rooms. He had had in view to get the temperature in the meridian room as far as possible identical with the outer one. There was constructed a new cupola for an equatorial of 8 feet, and a revolving roof for a new transit, to be used in different azimuths.

For the next day Prof. Förster proposed to visit Potsdam. There the just finished Astro-Physical Observatory should be inspected, and in the evening there would be a *soirée* given by the Government at Glienicke. Prof. Bruhns then read the report on the progress of cometary astronomy; in connection with it Prof. Gyldèn made some remarks on the computations by Dr. Backlund, of Pulkowa, of the absolute perturbations of Encke's comet by his new method.

There were proposed as places for the next meeting in 1881, Strassburg (Winnecke), Graz (Friesach), Brussels (Gyldèn); the election took place on the day following. Prof. Winnecke then gave, in support of his invitation to Strassburg, a detailed account of the new observatory now nearly finished there, and illustrated it with many drawings, representing the buildings, and explaining the manner of constructing the domes and laying the foundation for the pillars. There had to be provided observing rooms for the equatorial (object-glass 18 Paris inches), an orbit-sweeper (6 inches), the Repsold meridian-circle (6 inches), the altazimuth (5 inches), the Cauxoix-transit (5 inches), and different smaller instruments. There were a great many peculiarities differing from existing observatories, and Prof. Winnecke was very anxious to know if these innovations would turn out to be improvements.

Dr. Hasselberg (Pulkowa) spoke of the light emitted by gases induced by electricity and low temperature.

Dr. Drechsler (Dresden) reported on the collections of the Mathematical Saloon at Dresden, and distributed copies of a catalogue of them.

Prof. Saffarik (Prague) spoke on his observations on the colour of stars, principally on those of α Ursæ maj., the colour of which is said to be considerably and periodically variable. His own results do not confirm at all the supposed variability. This matter was then discussed between Herren Oudemans, Saffarik, and Winnecke.

Prof. Förster laid before the meeting (1) a volume, just published, in German, containing the observations of Dr. v. Konkoly at O'Gyalla; (2) different drawings of nebula from Herr Tempel at Arcetri; (3) an account by Dr. v. Konkoly of the new observatory, established in Hungary, at Kalocsa, by the Archbishop of Haynald. The director of this new observatory is Dr. Braun, well known by his attempts to register automatically the transits of stars.

September 6.—Prof. Auwers (Berlin) read the report on the principal undertaking of the Society, to fix by exact observation the places of all the stars down to the 9th magnitude, contained in Argelander's "Durchmusterung des nördlichen Himmels," the number of which is about 200,000. The observatories either busily engaged or having finished the part allotted to them in this work are: Nicolajew (Russia), Albany (U.S.A.), Leipzig (Germany), Lund (Sweden), Berlin (Germany), Leyden (Holland), Bonn (Germany), Helsingfors (Finland), Dorpat (Russia), Christiania (Norway), Kasan (Russia). The printing of some parts of the Catalogue will probably commence very soon, and it is to be hoped the grand work will be finished in a few years.

As the place for the next meeting (1881) the votes were nearly unanimous for Strassburg.

Prof. Gyldèn (Stockholm) expounded a new theory of the variability of stars, trying to reduce the problem to mechanical principles and expounding his views of overcoming the mathematical difficulties.

Dr. Schröder (Hamburg) gave an account of his proceedings in practical optics, aided by theoretical researches. As the hour of leaving for Potsdam was near, he delayed the exhibition of some specimens of his skill to Monday.

September 8.—According to the new elections made at the beginning of this meeting, the Council of the Society is composed, for the period 1879-81, as follows:—President, Prof. Krüger (Gotha); Vice-Presidents: Prof. Auwers (Berlin), Prof. Gyldèn (Stockholm), Prof. van de Sande Bakhuyzen (Leyden); Secretaries: Professors Schönfeld (Bonn), Winnecke (Strassburg); Librarian, Prof. Bruhns (Leipzig); Treasurer, Director Auerbach (Leipzig).

Prof. Tietjen (Berlin) read the report on the small planets, followed by a discussion between Herren Bruhns, Förster, and Oudemans.

Director Palisa (Pola) moved:—"To invite the Council of the Society to consider the means of arranging a better and more economical organisation of the present system of telegraphic announcement of new astronomical dis-

coveries." This motion, after some discussion, was carried unanimously.

Dr. Schröder (Hamburg) then finished the communication begun at the previous meeting. Herren Abbe (Jena), Saffarik (Prague), Bruhns (Leipzig), Winnecke (Strassburg), took part in the discussion on it. Prof. Oudemans (Utrecht) reported on the Gaussian object-glass of the Utrecht Observatory. Dr. Huggins (London) gave an account of his results in photographing star-spectra, and showed some of them to the meeting. Prof. Bruhns (Leipzig) exhibited drawings of nebula and neighbouring stars made by students of the University with small telescopes. Prof. Abbe (Jena) gave an elaborate account of his important theoretical and experimental researches in optics, followed by a discussion between him and Herren Förster and Winnecke. Prof. van de Sande Bakhuyzen (Leyden) explained his researches upon the dependance of the personal error in transit observations from the magnitude of the stars. Prof. Schönfeld (Bonn) reported on the progress of his "Durchmusterung" of the southern heavens. There is finished in observation at present about two-thirds of the whole work.

After a vote of thanks to the Prussian Government, the Royal Academy of Sciences, and the Berlin astronomers, the meeting of the International Astronomical Society was closed late in the afternoon. A. WINNECKE

INFLUENCE OF ELECTRICITY ON VEGETATION

SEVERAL months ago, it will be remembered, M. Grandeau described to the Paris Academy experiments made by himself and M. Leclerc at Nancy and Mettray, whence it appeared that flowering and fructification are retarded and impoverished if plants are excluded from the influence of atmospheric electricity—as by being inclosed in a metallic cage, or being near trees or other objects which may carry off electricity of the air.

Recently M. Naudin has repeated the experiments referred to, but with other plants and in a different climate, and, without wishing to contradict the conclusions arrived at for tobacco and maize (the plants that had been experimented with), he is led to regard the declarations made as too general, inasmuch as his results are almost exactly opposite to those obtained by MM. Grandeau and Leclerc.

It was at Antibes, in the large botanical garden formed by the late Thuret (now Government property), that M. Naudin made his experiments. He had an iron quadrangular cage made, covering a surface of fifty-one square decimetres, and about one metre in height; the frame carried points above (like small lightning conductors), and was covered with iron netting, the lozenge-meshes of this being 0·09m. long by 0·054 m. broad (it intercepted more light than M. Grandeau's, but this is thought insignificant). The cage was placed in a kitchen garden, and the plants it was made to inclose were kidney beans, lettuce, tomato, and herbaceous cotton (the last alone being sown as seed). In the same garden, at 7 metres distance, plants as like the others as possible were planted, and cotton seeds of the same kind sown, but without a cage-cover. The soil was perfectly homogeneous throughout, and all parts of the plot were equally exposed to sunlight, dew, and rain. The experiment began on May 25.

For a fortnight there appeared no sensible difference between the two portions; but about the middle of June it was remarked that the plants of the cage were stronger than those in the open air, and this difference became more pronounced as time went on. The plants, indeed, progressed side by side in this sense, that the flowerings were absolutely contemporaneous in the plants of the same species; and it was the same with formation and maturation of fruits. But it was quite otherwise with the quantity of vegetable matter produced in a given time and on the same extent of soil, and this difference was entirely in favour of the caged plants.

We may take the figures tabulated by M. Naudin for the tomato (examined August 14), as a good example of this:—

	Tomato in open air.	Tomato under the cage.
Length of the principal stem ...	0·80 m.	... 1·0 m.
Total weight of the plant cut at the level of the ground, fruits included	2·072 kg.	... 3·754 kg.
Number of ripe fruits and green fruits of all sizes ...	37	... 83
Weight of the whole of the fruit detached from the plant	1·80 kg.	... 2·162 kg.

The other plants gave a similar testimony in favour of the withdrawal of atmospheric electricity. Thus, the total weights of the bean plants were respectively 142 gr. and 167 gr.; and of the lettuce 337 gr. and 427 gr. The cotton plants were weakly (as there had been no watering), but their evidence was in the same line as that of the others.

The injurious influence, which, according to M. Grandeau's theory, trees exert on plants in their neighbourhood, by withdrawing atmospheric electricity, is also considered by M. Naudin to be only a special case. Besides, it is easy to ascribe to this withdrawal what is merely the result of the shade cast by trees, and especially of the exhaustion and desiccation of the ground by their roots, which often extend to a great distance. On the other hand there are many plants which seek the neighbourhood of trees, and which even thrive only under their shadow, and these, probably, must be adapted to a diminution of atmospheric electricity. At the Villa Thuret, M. Naudin remarks, there are several lawns quite inclosed by trees (pines, firs, cypresses, &c.), many of which are adult and of pretty good size. These lawns contain, besides their grass, thousands of anemones (*A. pavonina*, *A. cyanea*, *A. stellati*), some of pure race, others hybrid, whose flowers present all shades of red, rose, purple, white, and blue. The appearance is striking when the flowers come out in March or April. The flowering is not entirely contemporaneous throughout the lawn; it begins near the trees, and gradually extends to the middle of the lawn; the difference of time between these two extremes being twelve to fifteen days. Moreover, the anemones nearest to the trees, in addition to their relative precocity, are generally stronger and taller, and have broader, perhaps more brightly coloured corollas, than those in the middle of the lawn.

From the observations described, M. Naudin is disposed to think the question as to the influence of atmospheric electricity on plants is complex, and far from being decided as yet. This influence, in all probability, is modified first by the very essence of the species, which must behave, in regard to atmospheric electricity, as to other agents of vegetation, that is to say, in very diverse manners; then it is modified by climate, season, temperature, degree of light, dry or wet weather, perhaps also by the geological structure or mineralogical composition of the ground, the layers of which, superficial or deep, may not be equally conductive of electricity. It is possible, lastly, that all tree species may not alike withdraw the electric *effluves* of the atmosphere, and this is a point necessary to be determined. Until these numerous and so obscure conditions of the problem before us are sufficiently known, we should regard as premature any conclusion which is applied to the whole, or even only to the generality of the vegetable kingdom.

THE DIFFUSION OF LIQUIDS

IT is fortunate that various branches of the work with which Graham's name will always be connected are now attracting the attention of physicists. At the

beginning of this year Prof. Osborne Reynolds gave, in a remarkable paper,[1] the results of experimental researches "On Thermal Transpiration of Gases through Porous Plates," and showed the existence of a class of very marked phenomena which had escaped the notice of other observers. More recently Dr. John H. Long has studied the diffusion of liquids,[2] starting from the work of Graham, which must be regarded as the first and only general investigation of this subject we possess. Dr. Long's results will be briefly given in his own words, but it may be well to draw attention, as he does, to a few facts connected with the history of the subject. In two papers read before the Royal Society in 1850, Graham established that—

1. The velocity of diffusion is different for each substance in solution.

2. The amounts of salt diffused in a given time from solutions of the same substance, but different concentrations, are very nearly proportional to the concentration.

3. The amount of salt diffused from a given solution increases with the temperature.

Fick subsequently showed that liquid diffusion may be compared to the conduction of heat, that is, the spread of salt particles through water is in many respects analogous to the spread of heat in a conducting body, and that formulæ, similar to those established by Fourier for the latter case, may be applied in the former.

Certain experimentalists then employed optical methods of observation in determining the rate of diffusion of salts in solution, but Stefan showed that the optical methods "are based on a false assumption, and that they can therefore give only false results." It will be sufficient to state, however, that after a careful review of the work of the several investigators, Dr. Long divides the researches into two classes:—

1. Those which are concerned with the physical side of the question, that is, with the determination of "the constant of diffusion" for a single substance. To this class belong the researches of Fick, Simmler, and Wild, Voit, Hoppe-Seyler, Johannisjanz, Weber, and Stefan.

2. Those which treat the subject from a chemical point of view, by comparing the rates of diffusion of many different substances. To this class belong the investigations of Graham, Beilstein, and Marignac. Dr. Long points out that "in regard to the first class it may be said that a very satisfactory end has been attained. The proof of Fick's law by Weber and Stefan, and the determination of the influence of temperature and concentration of solution by the former, leave little to be desired in connection with this part of the subject. The same cannot be said, however, of the other, the chemical side." The experiments of Beilstein are not sufficiently numerous to establish much with certainty, and those of Graham and Marignac, while agreeing well among themselves, do not establish the dependence of diffusion on the molecular weight or other physical property of the substance employed.

Facts such as these have led Dr. Long to undertake a lengthy series of experiments, in which he employed a method that renders it possible to determine the rate of diffusion from hour to hour, and to insure that the diffusion takes place into a medium whose concentration is always zero. His apparatus may be roughly described as consisting of a U-tube placed in a beaker, which contains the solution to be investigated. The ends of the tube are bent over the beaker, one end being connected with a funnel into which water slowly drops, displacing the solution in the U-tube, which flows out from the other end at about the rate of 40 cc. in an hour. The base of the U-tube is open, and is connected with a short vertical tube whose internal diameter is 15 mm. This larger tube is open only at the bottom, and is arranged concentrically with the beaker.

[1] *Proc.* Roy. Soc., 1879, p. 304.

[2] A dissertation presented to the Faculty of Science of the University of Tübingen, 1879.

Diffusion thus takes place between the solution *below* the line of junction of the short tube with the U-tube and the water contained in the latter, the diffused particles being carried away and discharged; in other words, there is diffusion between a level of constant concentration and a level "of concentration zero." Space will only permit us to notice the general conclusions at which Dr. Long has arrived. He observes that no simple relation is recognisable between diffusion and other physical phenomena if we merely state the results in *grammes* of substance diffused. If, on the other hand, the results are stated as the numbers of *molecules* diffused, several interesting relations appear. For instance, it can be shown that the chlorides, bromides, and iodides of the alkaline metals form a series in which NH_4 stands between K and Na; and in this series the chloride, bromide, iodide, and cyanide of potassium have nearly the same rate. The chlorides of the dyad metals Ba, Sr, Cr, and Mg are also seen to form a series as to their rates of diffusion. It can further be shown, by comparing Kohlrausch's results on the electrical conducting power of liquids with the diffusion rates, that those salts which in solution offer the least resistance to the passage of the galvanic current are the ones which diffuse most rapidly. In most cases it appears that the salts having the greatest molecular volume diffuse the best, and those salts which absorb the greatest amount of heat on passing into solution are also the ones which diffuse most rapidly.

Dr. Long shows that Graham's view that no relation exists between the molecular weight and the rate of diffusion requires modification, for the alkaline chlorides, bromides, and iodides stand in the same order as regards molecular volume, rate of diffusion, conducting power, and latent heat of solution.

In conclusion Dr. Long indicates the direction in which he proposes to continue the research, which, we may add, bears evidence of being the work of an able physicist, from whom many valuable researches may be expected. W. CHANDLER ROBERTS

THE PARKES MUSEUM OF HYGIENE

THERE is one all important matter with which neither the great Institution in Bloomsbury nor that at South Kensington has virtually any concern; this important matter is Hygiene, the knowledge and application of the laws of life, which in so far as they are perfect banish disease from the human race. The Parkes Museum of Hygiene has been formed to promote this department of the numerous applications of science.

In the spring of 1876 the movement for the formation of the Parkes Museum commenced. It was the outcome of a very general desire to perpetuate in some useful way the memory of the late Dr. Parkes, whose life had been so unselfishly spent in promoting the welfare and happiness of his fellows by extending the knowledge of the laws of health, and whose untiring energy and keen intellect did such good service in clearing away the ignorance and superstition which accepted disease as the inevitable accompaniment of human life in this world. The movement rapidly developed into shape, and finally the Parkes Museum of Hygiene was opened to the public in June last, with a fairly representative collection of mechanical appliances, models, plans, and books, designed to promote health, of which a descriptive and illustrated catalogue was published. Since then so many valuable additions have been made to the museum that an enlarged and improved catalogue has been issued. The affairs of the museum are administered by an executive committee of which Sir William Jenner is chairman, and at present the cost of maintaining the museum has to be met wholly by voluntary contributions. The collection of appliances, models, &c., is temporarily located in the largest room of the south wing of University College, which, together

with a second room for the Library, has been generously placed at the disposal of the executive committee, by the council of the College, until such time as a separate building can be provided for the museum. The articles exhibited are arranged in six classes, and a brief description of these will serve to indicate sufficiently that the museum is likely to be of great service to those engaged in studying the sanitary construction of houses and other branches of hygiene. It should be stated that the classification is only a temporary one.

In Class I. (Engineering) will be found plans, sections, and models of systems of drainage for cities, towns, and villages, including the whole of the contract drawings used in connection with the construction of the present system of drainage in the metropolis. Maps, &c., illustrating the physical geography of this and other countries, plans of existing and proposed means of water supply for towns, sections of geological formations, and views of the position and surroundings of places noted as health resorts, apparatus in connection with water-supply, and the sinking of wells, are also included in this class.

Class II. (Architecture) consists of general designs for dwellings, hospitals, and other buildings, together with examples of the details of construction. This is by far the largest and most complete section of the museum; already it includes hundreds of models, or specimens of mechanical appliances, and modes of building construction—illustrating in detail the several parts of a well-built house, from the foundation to the roof—bricks, concrete, and other material for walls; artificial stone as a fireproof substitute for timber, &c., so commonly used for heads over door and window openings; also water-closets of every description; baths; stoneware, lead, and iron pipes; syphon and other traps; yard gullies, and contrivances for disconnecting the main sewers from the house pipes, may be seen and compared. Windows and doors so arranged as to give ventilation to the apartment in which they are fixed, stoves of various kinds, ventilating gas lamps, cowls for chimneys, and soil pipes, and other mechanical appliances designed to promote health in connection with architecture, make up this department.

In Class III. (Furnishing) are arranged specimens of school and household furniture presenting features of hygienic interest, including English and foreign oil lamps, specimens of wall papers, arsenical and non-arsenical; and here it may be interesting to state that the library of the museum has been decorated throughout with the new paint, in which zinc white is used as a substitute for white lead.

Class IV. (Clothing) is intended to include fabrics of various kinds used for clothing, with explanation of their properties and uses; but at present this class is only represented by some specimens of army clothing, and a few articles of dress coloured with arsenical pigments.

Class V. (Food) has been largely contributed by the authorities at South Kensington and Kew. It includes a number of large diagrams illustrating the component parts of food and the adulteration of articles of food in common use; samples of gluten bread and other foods for invalids; preserved fruits, seeds, &c.; different kinds of filters, and samples of water.

Class VI. (Preservation and Relief) is composed of all that relates to the hospital, the prevention of accidents or diseases peculiar to certain trades or occupations; disease charts, means for safety and rescue in case of fire, or accidents at sea; stoves for disinfecting purposes, Turkish bath apparatus, &c.

A library is being formed of books relating to hygiene. Exclusive of pamphlets, about 350 volumes are now deposited in the museum for reference, and in addition to these the reading-room is supplied with periodical publications and reports.

It will thus be seen that the Parkes Museum is fairly established. Owing to the limited means at the disposal of the Committee the museum is only opened to the public free on Tuesdays, Thursdays, and Saturdays, from 10 to 2 o'clock. This is perhaps a convenient time for architects, doctors, and other professional men, but it would be more completely supplying a public want if so beneficial an institution were opened during the evening, or at some such time when artizans and those actually engaged in building construction and sanitary work, might best avail themselves of the opportunities for gaining that enlightenment and knowledge which frequent and studious inspections of the contents of this museum of Hygiene would naturally afford them.

NOTES

THE building of the U.S. National Museum is approaching completion at Washington. It stands in the close neighbourhood of the Smithsonian Institution, but is of so different a style of architecture that it will not seem to dwarf the older structure by comparison. The area required for the museum, *Science News* informs us, is 327 feet to a side; in all, about 100,000 square feet, which is a somewhat greater space than the "Government Building" covered at the Centennial Exhibition; but is intended to be capable of holding and satisfactorily showing at least twice as many objects. The building is a square, with ornamental towers at the corners. It rises by a succession of clerestories to a centre surmounted by a dome. The height of the roof at the outer edge is 27 feet; the central room covered by the dome is 90 feet high. Exclusive of the towers, there are seventeen rooms in the interior, and of these apartments five are 65 feet square, four are 65 by 52, four are 91 by 52, and four are 101 by 65; the last mentioned being 45 feet high, and the rest of lesser heights except the one under the dome. The corner towers contain about 160 rooms, of which sixteen are 30 feet square, sixteen are 30 by 20, and the remainder are about 13 feet square, but arranged in suites of twos and fours. The larger of the tower-rooms will probably be kept for distinct collections, open to the specialist but not to the public. In the general exhibition rooms, there will be 5,000 feet of dead wall against which cases can be placed, and these if set end to end would extend over 8,000 feet. The total length of shelving in these cases will be 28,000 feet; the area, 74,000 square feet; a visitor who examines all the cases will traverse a circuit of nearly three miles. The museum will contain all that the Government displayed at Philadelphia; all the exhibits of foreign countries which were presented to the United States at the close of the Centennial show; the accumulations of the national surveys; the collections which are now overrunning the Smithsonian and the Patent Office, and a very extensive and complete exhibit of our fishing industries. Not a particle of wood will be used in constructing the building; hence it will be fireproof. It is to be warmed by steam in winter, and perhaps will be cooled in summer, so as to give a uniform temperature throughout the year.

THE death is announced of Dr. Eduard Fenzl, of Vienna, Professor of Botany and director of the Imperial Botanical Cabinet. Dr. Fenzl was a member of the Vienna Academy of Sciences and vice-president of the Vienna Horticultural Society. He died on September 29 last at the age of seventy-two years.

AT Baden-Baden the German geologists held their meeting after that of the German Association was over, viz., on September 26 and 27. Prof. Knop, of Karlsruhe, presided. There were some sixty members present from all parts of Germany and Austria. Mineralogical, geological, and palæontological papers were read by Professors Beyrich, Knop, Beneke, Häusler, Baumhauer, Eck, von Mojsisovics, and Tschermak.

THE American Association have selected Boston for their meeting next year, a pressing invitation from Sau Francisco

having meantime been declined. The president at the Boston meeting will be Prof. Morgan, of Rochester.

M. OTTO STRUVE, as our readers probably know, was recently in the United States, when he visited the works of Mr. Alvan Clark, the celebrated optician, and ordered an object-glass of 80 cent. diameter for Pulkowa's Observatory. We are informed that in consequence of that visit, Mr. Clark has gone to Paris in order to have the glass cast at M. Feil's works, rue Lebrun.

THE opening of the Practical School of Astronomy, of which we have already spoken, will take place very shortly at the Paris Observatory. The delay which has occurred has been occasioned merely by the absence of M. Ferry, who has been travelling through the whole of the provinces advocating in favour of Article 7 of his Education Law.

A NUMBER of scientific men are organising a Geographical Society in Algiers. The number of subscribers is not less than 200, and a general meeting has been convened for electing the officers of the Association. The success of that movement has led others to attempt the foundation of an Algerian Society for the Advancement of Science; but this is not likely to be successful, the attempt being premature.

PROF. PIAZZI SMYTH has been advocating the erection on one of the heights of Cyprus of a sort of Imperial Observatory, for which he thinks its clear atmosphere and sunny climate peculiarly adapted. He wonders how the British astronomers can exist at all in this cloudy and smoky climate.

THE following is the title of the essay to which the Howard Medal of the Statistical Society will be awarded in November, 1880. The essays to be sent in on or before June 30, 1880:—"The Oriental Plague in its Social, Economical, Political, and International Relations: Special Reference being made to the Labours of Howard on the Subject." The Council have decided to grant the sum of 20*l*. to the writer who may gain the "Howard Medal" in November, 1880.

THE Trustees of the British Museum are making arrangements to light the reading-room by means of the electric light. Waterloo Bridge has been lit up by ten electric lamps on the Jablochkoff system.

FROM a number of the *Otago Witness* which has been sent us we are pleased to see that science has not a few enthusiastic disciples in New Zealand. Prof. Black, of Dunedin, we are told, delivered the fifth lecture of the course in the chemistry lecture-room on July 12. For want of sufficient accommodation, the lecture was delivered twice—to the far-distance teachers, from 12.30 to 4 P.M.; and to the teachers resident in Dunedin and suburbs, from 5 to 9 P.M. As usual, the lecture-room was full on each occasion, about 180 teachers—80 of whom were ladies—being in attendance. Many of these came from a great distance. One gentleman came from Ngapara, 93 miles north from Dunedin; another from beyond Clinton, 75 miles south of Dunedin—thus bringing together teachers whose schools are 168 miles apart. About 20 of the teachers who attend these classes come more than 60 miles—from Lawrence, Oamaru, and beyond Balclutha. Over 60 of them come more than 30 miles. "Altogether, we believe," the *Witness* states, "the distances travelled to attend a course of lectures is quite unprecedented in any country, and our teachers are to be greatly commended for the interest which they take in the subject."

THE first meeting of the session of the Society of Medical Officers of Health will be held at 1, Adam Street, Adelphi, to-morrow at 8 P.M., when an inaugural address will be delivered by the president, Dr. J. S. Bristowe.

PROF. CORFIELD'S Introductory Lecture to the Ladies' Class of Hygiene and Public Health at University College will be delivered on Wednesday, October 22, at 3 P.M. The course will be continued on succeeding Wednesdays at the same hour.

IN the *Revue Scientifique* of September 27 is an interesting paper by E. B. Renault on the Comparative Structure of some Stems of the Carboniferous Flora.

AT Belgrade there were two shocks of earthquake on Friday and one on Saturday; on Saturday a shock was felt at the Roumanian town of Turn-Severin on the Danube.

DR. J. E. TAYLOR'S Winter Course of Lectures in connection with the Ipswich Museum will be on Flowers and Fruits. The average attendance at these lectures is 500 people, chiefly of the working class.

THE third part of Dr. Dodel-Port's excellent "Atlas der Botanik" is to be published within a few days. It will contain: (1) *Ulothrix zonata*; the most important points in the whole development of one of the lowest sexual chlorophyll *Algæ*. This treatise is an abstract of a monograph which the author published some years ago and which excited considerable interest at the time. The original treatise was noticed in these columns (vol. xv. p. 511). (2) *Polysiphonia subulata*; the fertilisation of a red sea-weed by animalcules, of which we gave an abstract a few numbers back (vol. xx. p. 463). (3) *Schizomycetes*; different types of putrefaction- and infection-fungi (with *Spirochæte Obermeieri*, the contagium of a certain typhoid disease). (4) *Bacterium anthracis*; the whole development of the carbuncle fungus according to the researches of Prof. Nägeli, of Munich, and of the author himself. (5) The development of the prothallium of the fern genus, *Aspidium*, from the spore to the formation of embryos. (6) *Cycas circinalis* and *C. revoluta*; female plant, female flower, carpel and fruit of the lowest flowering plant. Besides his "Atlas der Botanik," which involves years of hard work, Dr. Dodel-Port is about to publish a profusely illustrated work, "Bilder aus dem Pflanzenleben," which is written in popular language and is intended to bring the most interesting and most important questions of scientific botany before a larger public. The first part of this new book is to appear early in November.

AN interesting surgical case was recently reported by M. Larrey to the French Academy of Medicine. A young carpenter received a blow from an axe on his right foot. The big toe was almost completely detached; it was held merely by a small thread of skin, and hung on the side of the foot. Dr. Gavey, who was at once called in, detached the toe completely, then after having washed it and the wound on the foot, he adapted the two surfaces as well as possible one to the other, and made them hold together by means of strips of lint soaked with collodion and placed along the toe. When the collodion had set another strip was wound round. Further, an apparatus was used to keep all the parts of the foot in perfect immobility. Twelve days after, the dressing gave no bad smell, the patient was very well, and desired to go out, and twenty-four days after the accident the cicatrisation was perfect.

WE are sure our readers would welcome the very simple scheme proposed by Mr. Clifford Eskell for the giving of receipts by the Post Office officials for the posting of letters or other documents, at the cost of one farthing each. Mr. Eskell has forwarded us specimens of the "posting proofs" proposed by him, and they seem to us both simple and well adapted for their purpose. Some such arrangement as this would often save a world of trouble, and we trust that means will be taken to induce the Post Office authorities to give it a fair trial.

THE Smithsonian Institution, we learn from *Science News*, has lately added to its series of Check-Lists, one by Prof. A. E. Verrill, which originated in the useful purpose it would serve in the scientific work of the U.S. Fish Commission. It is entitled

"Preliminary Check-List of the Marine Invertebrata of the Atlantic Coast from Cape Cod to the Gulf of St. Lawrence." The paper, however, is not a complete catalogue. The whole of the groups Entomostraca, Nematoda, Rotifera, Trematoda, Cestoda, Acanthocephala, most of the sponges, and the protozoans, have been omitted. This is due to the fact that Prof. Verrill considers our knowledge of them too inadequate to justify a place in this check-list. The amphipods are represented by a blank, and the annelids leave room yet for many additions. Moreover, species not found at a depth of less than 200 fathoms are omitted, and likewise those from the Grand Banks of Newfoundland, which will be the subject of a separate publication. Despite these limited conditions of the work, a surprising number of marine invertebrates is catalogued—no less than about 11,000 species. Various signs and letters indicate the geographical distribution of many of the rarer species, and add value to the paper, which serves, among other uses, as a partial record of the zoological results of the Fish Commission's dredgings. As yet only a small "author's edition" has appeared; but a revised issue of a large number of copies will soon be sent out.

ON October 1 a double ascent, which produced some sensation at Paris, was made at La Villette gas-works. The balloons *European*, 650 cubic metres, carrying two aëronauts, and *Observatoire Aérien*, 350, carrying one, were sent up connected by a telegraphic wire of 120 meters weighing 1,500 grammes, and susceptible of a resistance of 15 kilogrammes without breaking. One aëronaut in each balloon carried round his body an inversion element and a Morse telegraph. Telegraphic signals were exchanged successfully during the connection, which lasted for thirty-three minutes, in spite of the differential motions of the air, which was in a state of rather great agitation. As it was very easy for the aëronauts to keep up conversation, no regular messages were sent through the wires. Other experiments will be made shortly with telephones, and a kilometre wire weighing 27 kilogrammes, and resisting a traction of 100 kilogrammes without breaking. In the experiment of October 1 the rope was disconnected only, because the aëronaut of the *Observatoire Aérien* expressed the wish to ascend to a greater height. As soon as the balloons were separated, each of them parted in a different direction. One of them landed in the north-east of Paris, and the other in the north-north-east. The separating force can be valued to the tenth part of the propulsion. The idea of sending up a couple of balloons connected by a telegraph or telephone wire must be attributed to M. Jovis, who was the captain of the *European*. M. Henry Ménier, the maker of telegraph wires at the Grenelle Works, has long entertained the idea of using the differentiation of velocity of each balloon with the current of air in which it is immersed for steering them with sail or rudder. He is to construct for this purpose a special cast-steel wire, susceptible of great resistance. It remains to be seen what is the practica bility of these and other schemes; but the fact of sending up two balloons so connected, and of keeping them in connection at will, unquestionably opens up a large field for future observations and scientific explorations which must be noticed.

MR. JAMES PATON, Curator of the Kelvingrove Museum, Glasgow, has prepared an interesting report of an official visit he paid recently to the museums and art galleries of Holland and Belgium. All the principal cities of these countries, he shows, are provided not only with magnificent art galleries, but with excellent scientific and technical museums, presenting an enviable contrast to most of the large cities of this much wealthier country. Mr. Paton reads the citizens of Glasgow a lesson which might well be taken to heart by other towns both in England and Scotland. "In point of population, wealth, and resources," he concludes, "not one of the towns alluded to in this report approaches the city of Glasgow. Taken altogether, their industries are fewer, less diversified, and less extensive, and their access to and command of markets, and consequently their opportunities for commercial development, are not equal to those enjoyed by our citizens. With less ability to maintain their great public institutions, and with less urgent necessity for them, on account of the limited industrial sphere of their inhabitants, these cities have put forth efforts on a scale which, if equalled in Glasgow, could not fail to have a most marked effect on the industrial standing of the city, at once elevating and refining the taste, stimulating thought and research, and suggesting new inventions and combinations. These institutions raise the whole mass of the population to a higher level, and they broaden and deepen the fertilising stream of industrial activity."

MR. EDWARD WHYMPER is about to issue a condensed and cheaper edition of his "Scrambles Amongst the Alps" under the title of "The Ascent of the Matterhorn." It will be published by Mr. Murray. Among other forthcoming books to be published by Mr. Murray we notice the following:—"A History of Ancient Geography," by E. H. Bunbury, F.R.G.S., with index and maps; "The River of Golden Sand," being the narrative of a journey through China to Burmah, by Capt. Wm. Gill, R.E.; in two volumes, with a map and illustrations; "A Lady's Life in the Rocky Mountains," by Isabella Bird; "A Sketch of the Life of Erasmus Darwin," by Charles Darwin, F.R.S.; with a Study of his Scientific Works, by Ernest Krause, translated by W. S. Dallas.—Messrs. Crosby Lockwood and Co. have nearly ready for publication a "Treatise on Metalliferous Minerals and Mining," by D. C. Davies, F.G.S., Mining Engineer. The book will be illustrated with numerous wood engravings.—Mr. David Bogue has in the press a Manual of the Infusoria, by Mr. W. Saville Kent, F.L.S. The volume will comprise a descriptive account of all known Flagellate, Ciliate, and Pentaculiferous Protozoa, and will be accompanied by numerous illustrations; it will probably be ready in March next. Mr. Bogue will also publish shortly a work on the "Sphagnaceæ, or Peat-Mosses of Europe and North America," by Dr. R. Braithwaite, F.L.S. This will be illustrated with twenty-nine plates.—Messrs. Kegan Paul and Co. will publish during the ensuing season the following books bearing upon science:—"The Crayfish: an Introduction to the Study of Zoology," by Prof. T. H. Huxley, F.R.S.; with numerous illustrations; "The Brain as an Organ of Mind," by H. Charlton Bastian, M.D., F.R.S.; with numerous illustrations; "The Brain and its Functions," by J. Luys, Physician to the Hospice de la Salpétrière; with illustrations; "The First Principles of the Exact Sciences explained to the Non-Mathematical," by the late Prof. W. Kingdon Clifford; edited by R. C. Rowe, M.A. The above four books are new volumes of the *International Scientific Series*. "Hygiene and the Laws of Health," by Prof. Corfield, M.D.; "Chapters from the Physical History of the Earth: an Introduction to Geology and Palæontology," by Arthur Nicols, F.G.S.; with illustrations; "Matabele Land and the Victoria Falls: a Naturalist's Wanderings in the Interior of South Africa," by C. G. Oates. "An Introduction to the Science of Language," by the Rev. A. H. Sayce, Deputy Professor of Comparative Philology in the University of Oxford; in two vols. —The first volume of Prof. G. G. Stokes' "Mathematical and Physical Papers," reprinted, with additional notes by the author, from the Original Journals and Transactions, in which they appeared, is now nearly ready. It will be published by the Cambridge University Press.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. W. Leekie; five Peregrine Falcons (*Falco peregrinus*) from Scotland, presented by Sir Mathew W. Risley, Bart., M.P.; four Green Tree Frogs (*Hyla arborea*), a

Fire-bellied Toad (*Bombinator igneus*), a Natterjack Toad (*Bufo calamita*), European, presented by Mr. H. A. Macpherson; six Green Tree Frogs (*Hyla arborea*), European, presented by Mr. A. Leipner, F.Z.S.; a Chacma Baboon (*Cynocephalus porcarius*) from South Africa, deposited; two Rendall's Guinea Fowls (*Numida rendalli*) from West Africa, a Javan Peafowl (*Pavo spicifer*) from Java, three Royal Pythons (*Python regius*) from West Africa, received in exchange; two Saffron Finches (*Sycalis flaveola*), bred in the Gardens.

SOME RECENT EXPERIMENTS ON THE CRYSTALLISATION OF SUPERSATURATED SALINE SOLUTIONS [1]

THE history of the various views held by different experimenters on the nuclear action of substances in exciting the sudden crystallisation of a supersaturated solution, has been already so well described by Mr. Charles Tomlinson, Prof. Liversidge, Prof. Grenfell, and others in their several papers upon the subject, that it is unnecessary to enter into any detailed description of their opinions; suffice it to say that they may be divided into two classes: the first holding the opinion that the crystallisation may be excited by the presence of certain fatty, oily, greasy, or other matters in the form of films; the second that the initial cause of the crystallisation must be sought for in the entrance of a particle of the same salt as that which is in solution.

In 1866 M. Gernez indicated that in the case of certain salts the sudden crystallisation might be brought about by the agency of some other salt perfectly isomorphous with the one in solution; thus a supersaturated solution of magnesium sulphate invariably crystallised when crystals of zinc or nickel sulphates containing seven molecules of water in their composition were introduced. Having been for a long time interested in the crystallisation of such solutions, I determined to carry out a large number of experiments upon carefully purified substances which observations have resulted in a confirmation of the views held by Gernez that truly isomorphous substances are active to solutions of each other.

The two methods employed in the experiments may be briefly stated as follows:—(1) The supersaturated solutions of the salts to be examined were placed in small wide-mouthed flasks; and the solutions of the salts employed as nuclei were introduced into very thin glass bulbs plugged with cotton wool, and suspended through a second plug of cotton in the neck of the flask, in a manner such as is indicated in Fig. 1. (2) A large number of the experiments were also performed by using, instead of the bulb tube for the introduction of the salt employed as nucleus, a tube bent as a siphon, thus ∩J, and like the bulb tube passing through cotton wool plugs in the necks of the flasks; the whole arrangement when complete being as represented in Fig. 2. To perform an experiment the solution in the bulb or in the siphon tubes was crystallised, and after a short time these tubes were gently lowered into the solutions in the flasks and the results observed. When the bulb tubes were used they were gently broken against the bottom of the flask, the contained crystals being thus brought in contact with the solution. To show that the disturbance produced by this breaking had of itself no exciting action on the solutions in the flasks, corresponding experiments were made with bulbs containing clean pieces of glass, when no crystallising action took place, showing that the mere disruption of the solution did not cause crystallisation. The largest number of experiments were, however, carried out by the siphon tube method, which is perfectly applicable after a little practice in the introduction of the tubes. The substances employed were in all cases carefully examined to ensure their purity.

With magnesium sulphate ($MgSO_4 . 7H_2O$) as a supersaturated solution, it was found that the other sulphates of the same group of metals, namely, those of zinc, nickel, cobalt, and iron, were immediately active in causing the crystallisation of the magnesium solution when they possessed an identical composition with it, as represented by the general formula ($M''SO_4 . 7H_2O$), M representing the different metals. When these salts contained only six proportions of water crystallisation is sometimes induced, but in this case it is of an entirely different nature, the deposition being slow and gradual. In connection with this group of salts interesting results were obtained with the double salt potassio-magnesic sulphate ($MgK_2(SO_4)_2 . 6H_2O$), crystals of which, although possessing the elements of magnesium sulphate, were found inactive to a solution of that body. In the case of supersaturated solutions of sodium sulphate ($Na_2SO_4 . 10H_2O$), the bodies sodium selenate ($Na_2SeO_4 . 10H_2O$), and sodium chromate ($Na_2CrO_4 . 10H_2O$), each analogous in form and constitution to the sulphates but containing the elements selenium and chromium instead of sulphur, were found capable of exciting crystallisation in solutions of the sulphate.

Experiments were also performed upon supersaturated solutions of potash alum ($AlK(SO_4)_2 12H_2O$), with crystals of iron and chromium potash alums, bodies agreeing in form and constitution with common alum, but containing chromium or iron in place of the metal aluminium. These bodies were found invariably active in exciting the crystallisation of the common alum solution. As alum crystallises in beautiful octahedral crystals some experiments were made to see how far the mere shape of the crystal could render it active in exciting the crystallisation; and for this purpose cubes of copper pyrites and octahedra of magnetite, both belonging to the same crystalline system as alum but having a different chemical structure, were employed. When these substances in a perfectly clear condition were placed in the alum solutions no sudden crystallisation was produced, showing that mere form alone is inactive in exciting this kind of crystallisation. Crystals of hydric disodic arsenate ($Na_2HAsO_4 . 12H_2O$) were also found active in the case of the isomorphous hydric disodic phosphate, containing phosphorus instead of arsenic, but otherwise analogous in form and composition. In connection

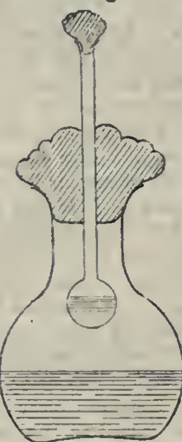


Fig. 1.

Fig. 2.

with this latter salt it is worth noting that when the hydric disodic phosphate is heated to convert it into sodium pyrophosphate ($Na_4P_2O_7$), this substance is no longer active to a supersaturated solution of the disodic salt. At the same time corresponding experiments were performed on the supersaturated solutions of magnesium sulphate, alum, &c., with substances of dissimilar form and chemical constitution; these bodies, however, invariably yielded negative results, being incapable of exciting the sudden crystallisation of the solutions.

Experiments carried out upon mixtures of similarly constituted and dissimilar bodies, yielded some interesting results. The substances employed were mixtures of the similarly constituted sulphates of magnesium and nickel, and the dissimilar sulphates of magnesium and sodium; experiments were also made with sulphates of nickel and sodium. In the case of these mixtures it was observed that two results might occur:—(A) The nucleus might remain growing in the solution without causing immediate crystallisation; or (B), Crystallisation might be induced at once on the addition of the nucleus; the deposition of the salts, however, differs according to the nature of the substances employed.

In the case of the dissimilar bodies, magnesium or nickel sulphates with sodium sulphate, it was found that a nucleus of either sulphate when gradual crystallisation took place, slowly increased by a deposition of the substance of the same nature as the nucleus added; and that even with the rapid crystallisation of dissimilar bodies the salt deposited consisted essentially of the substance of the same nature as the nucleus added.

[1] Abstract of a paper read before the Chemical Society on March 6, 1879.

With mixtures of isomorphous salts, however, the results were different. In these cases sudden crystallisation on touching with a nucleus producing a separation of both the sulphates apparently always in the proportions in which they existed in the solution. When gradual crystallisation took place with the sulphates of nickel and magnesium the nucleus increased by a deposition of the least soluble salt independent of the nature of the nucleus added. It may be seen therefore from these experiments that truly isomorphous bodies, that is, substances not only possessing the same form but also an identical chemical structure, may be regarded as active nuclei in exciting the sudden crystallisation of supersaturated solutions of each other. I hope shortly to extend the observations upon supersaturated solutions of mixtures, and of compound salts, employing their different constituents as nuclei, as I think by such experiments some light may be thrown upon the relations between these constituents when associated together in solution. There are, however, very few true double salts of which it is possible to obtain thoroughly supersaturated solutions.

JOHN M. THOMSON

ON THE EARLY STAGES OF THE CÆCILIANS

THERE are few groups of vertebrates respecting whose life-history and development so little is known, as the curious snake-like amphibians forming the order *Peromela*, and usually known as Cæcilians. In all the ordinary zoological text-books in use in this country, the early stages of these animals are either left entirely unnoticed, or, at most, allusion is made to Johannes Müller's classical discovery of gill-slits in the young of *Epicrium glutinosum*. Even Prof. Huxley, in his article on the Amphibia in the first volume of the "Encyclopædia Britannica," published in 1875, after an allusion to Müller's discovery, states:—"It is to be regretted that nothing is known of the development of the Peromela" (*loc. cit.* p. 770).

This being the case, it may be useful to call attention to two papers on the development of the Cæcilians, by Dr. Peters, the eminent German naturalist, read by him before the Royal Academy of Sciences of Berlin, and published in their *Monatsberichte*, as their contents seem to be unknown to, or overlooked by, the bulk of English zoologists. The first of these bears the date of January, 1874, the second was read eighteen months later (July 19, 1875). In the first of these Dr. Peters, after noticing the discovery by Müller of gill-slits in *Epicrium*, and its subsequent confirmation by himself (*cf. Monatsbericht*, 1864, p. 303) continues, "it was therefore extremely interesting to me to learn from Prof. Wrzensniowski of Warsaw, who last summer honoured me with a visit, that some years ago the naturalist-traveller Constantin Jelski had sent him from Cayenne a gravid *Cæcilia*, which after its capture had given birth to a young one, and had contained in its uterus several full-grown embryos. Herr Wrzensniowski has now sent me for examination three of the young ones, and the old animal, referable to *Cæcilia compressicauda* (Dum. and Bibr.), and has given with them the following notes, part of which are extremely interesting." These notes are extracted from a letter of Jelski's, dated from Cayenne, November 12, 1866, to Herr Taczanowski, the well-known Polish zoologist, in which he gives his account of an expedition to East Guiana, to a plantation called "Bon Père," belonging to a M. Lalanne, from which he had just returned. After narrating the method of fishing by means of nets adopted, and the great abundance of fish, Jelski continues—"'In the course of the hunt, the negro who was frightening the fish away from the bank, suddenly uttered a loud cry: we all saw something that looked like an electric eel swimming about with worm-like movements just under the surface of the water. M. Lalanne and I held back the negro, who was about to cut the animal into bits with his sword, the net was hauled up, and the creature landed. We all thought it was an eel, but on closer examination decided that it was a gigantic water-worm. I put the creature into a special vessel, and as I had already fish enough, and did not hope to obtain any others, went home. As I was taking this problematical creature out of the vessel, to put it into the calabash, I saw two of them instead of one. The old one had produced a young one. After I had laid the old one on the table, I examined it more closely; it exhibited very slow, tremulous, slight movements. Shortly afterwards I found it in true convulsions. I perceived that it was about to produce a second young one. I placed it in spirit, so as to convince people of its being viviparous. Membranes (*Häute*) were ejected together with the first young one.' Herr Wrzensniowski adds—'After the receipt of the animal, I dissected it myself, and found in the oviduct five young, which I at once extracted, and two of which I send you together with the one that was born in Cayenne. All these examples that were removed from the oviducts were remarkable for a membranous outgrowth on the necks which was very easily torn off, and left a transverse linear scar, as in the specimen born in Cayenne, so that only a single specimen has retained this outgrowth till now. In the uterus I perceived nothing else noteworthy; the embryos lay in a dilatation of both oviducts, just as they now are in the spirit, without being covered by any membranous envelopes. I conclude therefore that the membranes, which, according to Herr Jelski, were extruded together with the young one from the oviduct were nothing else than the shed neck-vesicles (*Nackenblase*), which we could not find again in the parcel from Cayenne.'"

"The female forwarded to me, whose oviducts had been removed, was fifty cm. long, and four cm. deep in the middle; its head measured three cm.; of the young ones, the newly-born one, and one of the embryos, had a length of 157 millims., and a depth of twelve millims.; their heads measured eleven millims.; the other was only 136 millims. long and twelve millims. deep; its head was ten millims. They show no trace of the skinny vertical swimming-tail (*Flossensaum*) which both J. Müller and myself found on the hinder ends of the young *E. glutinosum*. But what surprised me much more was that there was no trace to be found of lateral gill-openings, like those which have now been discovered in several young examples of *Epicrium glutinosum*. The head and fore part of the body in all three specimens lay bent back towards the sides of the belly, so that apparently in the uterus this curved part, that is the under side of the head, is closely applied to the body, and the end of the body also seems to have been recurved towards the sides of the belly. From the neck of the one specimen two smooth vesicles, fifty-five millims. long, of irregular shape, and variously constricted, project; on them a blood vessel ramifies, whilst at their narrow transverse base they are connected together, though unfortunately no more can be learnt as to their original position, except that from their flat convex-concave form they are probably closely applied to the body.[1] On the transverse scar, where the epidermis is absent, which these vesicles leave after falling off, on each side a small hole is visible, the lumen of one or two vessels, which are in connection with the aortic arches of their side. These vesicles therefore are external gills, which resemble the bell-shaped external gills which Dr. Weinland discovered in the larvæ which develop in the external dorsal pouch in the female *Notodelphys* (*Opisthodelphys*) *ovifera*, and which he has described so well and thoroughly (Müll. *Archiv*, 1854, p. 457, Taf. xviii., Fig. 5, 6)." After some prefatory remarks on the distribution of the vessels to these bladder-like gills, Dr. Peters concludes:—"In any case, this discovery of a new agreement in the development of the Cæcilians with the other Batrachians is one of the greatest scientific interest, for in fact, not only is there now no doubt that, as in the *Anura*, so also amongst the Cæcilians a different gill-structure (*Kiemenbildung*) obtains, but it can also now be stated with certainty that in these animals also, for which the establishment of a third class or sub-class of Amphibians has even been proprosed, no amnion or allantois are developed, that, in part at least, they are viviparous, and that, at a certain period of the year, they are to be sought for, not in moist earth, but in water. Moreover, it is extremely probable that these animals, which only occur to fishermen rarely, and at a certain season, are not recognised by them, but are in fact shunned and destroyed on account of their ugly and worm-like aspect, and on this account so rarely come into the hands of collectors in their larval state."

In his second paper, read July 19, 1875, Dr. Peters contributes some further notes on the same subject, giving figures illustrating the young *Cæcilia* with its bladder-like gills still *in situ*, as well as the scars left on the neck after the fall of the gills, and the distribution and relations of the great vessels and aortic arches. The bulk of the paper is taken up with an account of the anatomy of the young Cæcilians, but a few additional remarks on other points are given which we here reproduce. "As was there (*i.e.* in his first paper) stated, in this species the embryos at birth are at most three and two-thirds smaller than the mother. It is also known that the young of *Epicrium glutinosum*, in which

[1] This is also very probable from the observations of Weinland on *Opisthodelphys ovifera*, where the bell-shaped gills envelope most of the body.

the lateral gill-slits are still visible, are even larger as compared with the parent animal than is the case in *Cæcilia compressicauda.* According to this, one might almost believe that such a relation in size is universal in the embryo Cæcilians. On the other hand, one might conjecture that a development with external vesicular gills, which obtains only exceptionally amongst the *Anura*, as in *Opisthodelphys* and *Nototrema*, occurred more commonly amongst the Cæcilians. The few observations however which have as yet been made on the other species of Cæcilians do not confirm this. Thus A. Dumeril, in a young *C. oxyura*, 50 millims. long, has found on each side of the neck a branchial cleft, which it is true lies somewhat higher than in *E. glutinosum*, but still proves that in this species no external vesicular gills are developed (*Mem.* Soc. Sc. Nat. Cherbourg, ix., taf., 1 Fig. 8). Further, Prof. Möbius on the occasion of his late visit to the Seychelles, brought back several examples of *C. rostrata* (Cuv.), of very varying sizes (from 35 to 240 millims.) which have neither branchial clefts, nor a swimming-tail, nor do they show the scars on the neck that accompany the vesicular gills. All this leads one to conclude that the development of the Cæcilians, like that of the *Anura*, goes on in very various ways, and that in this field too important discoveries are still to be made. It cannot therefore be too deeply impressed on naturalists who visit tropical countries where Cæcilians are found, to give to this subject their especial attention."

PHILOSOPHY OF THE PUPATION OF SOME BUTTERFLIES[1]

THE comparatively sudden transitions from one state to another in insects, have always excited the keenest interest. The change from larva to chrysalis in those butterflies known as *suspensi*, and which in the chrysalis state hang from the tip of the body, has, perhaps, been looked upon as the most wonderful. The preliminary acts in the performance have been pretty well observed and described by various authors since the days of Vallisnieri. The larva hangs by the anal end, turning up the anterior part of the body in a more or less complete curve, and the skin finally splits from the head to the front edge of the metathoracic joint, and is worked back in a shrivelled mass towards the point of attachment. Now comes the critical feat which has most puzzled naturalists, viz., the independent attachment of the chrysalis and the withdrawal from, and the getting rid of, the larval skin which such attachment implies.

Réaumur explained it in 1734 by the clutching of the larval skin between alternate sutures of the soft joints of the chrysalis; and his happy and circumspect account from observations made on *Vanessa urticæ* has formed the basis for subsequent accounts; no one obtained a deeper insight into the philosophy of the act until, some two years since, Dr. J. A. Osborne, of Milford, England, discovered that a distinct membrane is concerned in it. In casual observations of the process I had long become convinced that the popular accounts were crude and inaccurate, and I had preserved specimens in the act of transforming, for future study; but the philosophy of the change cannot be satisfactorily made out from alcoholic specimens alone, nor from the study of one species. The present paper is based on observations made on species belonging to more than a dozen genera, the conclusions having been partially presented last June to the Philosophical Society of Washington.

The body of the larva is composed (exclusive of the head) of twelve segments or joints, *and a sub-joint.* It is with this sub-joint that we have here to deal, for to it beneath the rectum are appended the anal pro-legs, and above this is the anal plate.

If we carefully examine the anal plates of the larvæ of the true *suspensi*, we shall find that while they differ in form they have one feature in common, viz., the being furnished dorsally and posteriorly with numerous short spines and points generally retrorse, or so placed that the larva can make use of them in suspending. These special spines on the anal plate are only fully developed after the last larval moult, being more or less obsolete in the earlier stages, and they are also under muscular control. Even in the *succincti*, where, as a rule, the anal plate is not specialised, spines are, nevertheless, sparsely found, especially on the border.

All writers whom I have consulted speak of the larval suspension being due to the entanglement of the hooks of the anal pro-legs in the silk, and do not mention the use of the anal plate, for which the hillock of silk is sometimes spun in special form.[1]

The normal form may be likened to that of an inverted settee, or shoe, or to a ships-knee, and one of the most interesting acts of the larva, preliminary to suspension, is the bending and working of the anal parts in order to fasten the back of the plate to the inside of the back of the settee, while the crotchets of the legs are entangled in the more flattened position or seat. In some cases (as in *Danais*) the hillock of silk is more elongate, and the spines of the truncate plate mostly occur around the lower margin and even beneath it, so that in fastening them the larva seems to be drawing the silk up the rectum. In other cases (as in *Euptoieta*) the plate, in addition to the spines, has a prominent tubercle on each anterior outer border well calculated to lock securely into the silk. After suspension, and as the fluids gravitate anteriorly, the silken hillock becomes more conical (the threads being loosely spun and elastic) and the hooks both of the plate and the pro-legs hang more loosely from it.

In the final getting rid of the larval skin and attachment of the chrysalis there are concerned—

1. Certain factors belonging to the larva and cast off with its skin. 2. Those belonging to the chrysalis; and to intelligibly explain the process it is necessary to more fully characterise and homologise these parts than has hitherto been done.

In the former category, in addition to the natural adhesiveness of the moist, mucous, and membranous corium,[2] there are three physiological factors concerned: (1) the *tracheal ligament*, or the shed tracheæ from the last or ninth pair of spiracles which uniformly become blind or obsolete in the chrysalis; (2) the *rectal ligament* or shed intestinal canal; (3) the Osborne or retaining membrane (*membrana retinens*), which is but a stretched part of the membranous corium that accumulates around the rectum and in the anal pro-legs.

In the second category we have the structural features of the chrysalis. These are, first, the *cremaster* proper, which is the homologue of the anal plate of the larva, and the form of which is foreshadowed in that of said anal plate. This cremaster assumes a great variety of different forms, but in general may be said to be a tapering piece more or less incurved ventrally, and having the ventral and dorsal margins thickened or ridged, and these ridges may be respectively called the *ventral* and the *dorsal cremastral ridges*. This cremaster is surmounted at the apex and sometimes along the ventral ridges by what may be called the *cremastral hook-pad*, thickly studded with minute but stout hooks, which are sometimes compound or furnished with barbs very much as are some of our fishing-hooks, and which are most admirably adapted to the purpose for which they are intended.

Secondly, we have the sustainers (*sustentores*), two projections which homologise with the soles (*plantæ*) of the anal pro-legs, and which take on various forms, but are always directed forward, so as to easily catch hold of the retaining membrane. In the yellow butterflies (as *Callydrias*, *Terias*, *Colias*), where the body of the chrysalis is so thrown back that mere projecting tubercles would not suffice, we find them transformed into actual hooks; while in some of the *succincti* they are little more than a thickening of the anterior margin of the sub-joint. In all lepidopterous pupæ these remnants of the anal pro-legs are more or less indicated, while in certain moths (*Pterophoridæ*) where the pupa is partly suspended, they are, as in the *Nymphalidæ*, covered with long hooks similar to those at the tip of the cremaster.

Thirdly, we have what may be called the *sustentor ridges*, usually connected with the sustainers, embracing them on the outside, and extending backward to the inside of the ventral cremastral ridges, and sometimes, as in *Paphia* and *Limenitis*, forming quite a deep notch, which doubtless assists in catching hold of the larval skin in the efforts to attach the cremaster.

[1] Abstract of a paper read before the American Association for the Advancement of Science, by Prof. C. V. Riley.

[1] It is an interesting fact in this connection that Roesel, who has never had any superior as a delineator of insect larvæ, makes the Nymphalids in his figures all suspend to an elongate conical piece of silk apparently issuing from the anus, with the legs invariably free and in no instance hooked. It is evident, however, from his text, that he was not aware of the use of the anal plate, and since he speaks of the larvæ attaching themselves by the bind legs or extremities, it is equally evident that his figures do not correspond with the text, while the freedom of the legs in his figures is, of course, an error

[2] What is here termed the *corium* is the membranous layer between the separating larva skin and the forming chrysalis. If, as recent investigations seem to show, it is only the outer half of the dermal layer of the skin which is cast off in the exuviation of invertebrates, and not the whole skin with its three layers, then this membrane is developed between the splitting parts of said outer layer, and is not, strictly speaking, the *corium*.

These sustentor ridges are homologous with the limb of the anal pro-legs and the exposed edge with the posterior border of said limb. They vary much in form, and may be more or less obsolete.

Fourthly, between them is what may be called the *rectal piece*, consisting of a piece more or less well marked and elevated, especially around the closed rectum.

It is principally by the leverage obtained by the hooking of the sustainers in the retaining membrane, which acts as a swinging fulcrum, that the chrysalis is prevented from falling after the cremaster is withdrawn from the larval skin. It is also principally by this same means that it is enabled to reach the silk with the cremastral hook-pad. Yet the rectal ligament plays a most important part, and in some species a more important part even, in my estimation, than the membrane itself. The tracheal ligaments which, from a study of specimens plunged in alcohol when the larval skin was about half shed, I was at first inclined to believe important auxiliaries, are, I am now satisfied, of very little if any service in most cases. The rectal ligament is a constant physiological factor, and its importance cannot be ascertained by attempts to sever the membrane at the critical moment, because in such attempts the ligament is more or less drawn out beyond the power of the sphincter muscles in the chrysalis to control it.

Dissected immediately after suspension, the sub-joint of the larva will be found to be lying, especially between the legs and around the rectum, in an abundance of translucent, membranous material. An hour or more after suspension the end of the forming chrysalis begins to separate from the larval skin, except at the tip of the cremaster. Gradually the skin of the legs and of the whole sub-joint stretches, and with the stretching the cremaster elongates, the rectal piece recedes more and more from the larval rectum, and the sustentor ridges diverge more and more from the cremaster, carrying with them, on the sustainers, a part of the soft membrane. If a larva be carefully dissected at this stage, the forming membrane may be raised with the point of a needle, and stretched so as to show its connection with the rectal ligament; or it may be lifted entirely from the retainers, when, by its elasticity, it contracts, and becomes more or less fully absorbed in the rectal ligament. It is at this stage that the strength of the latter may be fully tested, and if the chrysalis, flayed from the larval skin, and freed from the retaining membrane, be grasped in the neighbourhood of the rectum, so as to supply the natural holding power of the sphincter muscles, the rectal ligament will sustain, as I have abundantly proved, at least ten or twelve times the weight of the chrysalis; while it will support, if held by the larval skin, several times the weight of the chrysalis before separating therefrom. In brief, the retaining membrane is that part of the inner larval skin surrounding the pro-legs drawn down by the sustainers, and always intimately connected with and forming but a branch of the rectal ligament. When extended from its attachments, as when the chrysalis rises to the silk, this membrane dries, and in the cast-off larval skin retains more or less perfectly the stretched form. If the corium of the larva be thick and strong, as in *Vanessa*, the dried membrane will be broad, with two indentations where it was held by the retainers; if the corium be more delicate, as in *Danais*, *Paphia*, or *Apatura*, the dried membrane will be more forked, showing how the retainers have acted upon its elasticity. In every case, however, it shows, under the microscope, the longitudinal folds and creases incident to the stretching, and, compared to the rectal ligament proper, it seems to lose importance as it is less needed; for the *succincti* will generally attach when it is severed or loosened from the retainers, while in *Apatura* (at least as exemplified in the North American species), which combines the peculiarities of both the *succincti* and *suspensi*,[1] it does not become specialised, and the chrysalis seems to rely almost entirely on the rectal ligament, assisted by the partial holding of the delicate larval skin, not only between what is left of the sustainers and the ventral posterior margin of the twelfth joint, but between the ventral sutures of this last and the preceding joint. And here I would remark, in conclusion, that the ventral borders of two or three of the joints preceding the subjoint are, in most chrysalids which I have studied, so hardened that the larval corium is actually grasped between them and the deep sutures made in contracting. In some instances (especially in some species of *Papilio*) the posterior border of the twelfth joint is produced into a medial transverse ridge fully as prominent as that formed by the sustainers, which here are flattened and coalesce; so that the sutures of some of the terminal joints in the chrysalis do subserve the purpose ascribed to them by Réaumur, but in a somewhat different way.

[1] The larva of *Apatura* attaches horizontally, making the front pair of abdominal pro-legs answer the purpose of the girth; but in the shedding of the skin this attachment is severed, and the forming chrysalis assumes the perpendicular position, and in the withdrawal and attachment of the cremaster it acts as the true *suspensi*.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

THE Oxford *University Gazette* of October 10 contains counsel's opinions on the proposed faculty of Natural Science at Oxford. It has been proposed that the University should, by statute, establish a new faculty, under the name of "The Faculty of Natural Science," should grant degrees of Bachelor and Master in that faculty, and should give to Masters of Natural Science all the rights and privileges which are now enjoyed by Masters of Arts, so making them Members of Convocation (the governing body of the University), and enabling them to vote for the members returned to Parliament by the University. Mr. Horace Davey is of opinion that the University may create a new faculty in science, or (which comes to the same thing) may sever one of the sciences or philosophies formerly comprised in the Faculty of Arts, and may make it into a new faculty, and grant degrees therein. Such a severance was anciently made in the case of grammar, rhetoric, and music. But Mr. Davey believes that the University has no power to confer upon graduates in a new natural science faculty the rights which now belong to Masters of Arts, and the degree of Bachelor or Master of Natural Science would not make the holder a Member of Convocation. This difficulty Mr. Davey suggests, might be avoided by the University conferring the degree of Master of Arts on any person obtaining the corresponding degree in the new faculty.

The new chemical laboratories at the Oxford University Museum will be opened for students this term. The chemical department has now for many terms been overcrowded, and the new buildings will not only afford ample space for beginners and pass-men getting up their "simple salts," but contain rooms set apart for special work and fitted with the best appliances under the careful superintendence of Mr. W. W. Fisher, Aldrichean Demonstrator.

The new chemical laboratory at Balliol College will be opened this term under the superintendence of Mr. H. B. Dixon. Balliol and Trinity Colleges have combined to equip and maintain this laboratory, and a physical lecture room for the use of their own students.

At the University Museum Prof. Odling will lecture, this term, on Organic Chemistry; Mr. Fisher will lecture on Elementary Organic, and Mr. Donkin on Elementary Inorganic, Chemistry. Prof. Clifton will lecture on Elementary Electricity, and Prof. Story-Maskelyne on the Use of the Goniometer. Prof. Prestwich gives a course on two afternoons a week, on the Palæozoic Rocks, at the Museum, and Prof. Lawson will lecture on Vegetable Histology, at the Botanic Garden. Rev. C. Pritchard, Savilian Professor of Astronomy, will give practical instruction at the University Observatory, on fine evenings during the term; he will also continue giving public lectures on the history of astronomy. Dr. Rolleston will lecture on Circulation and Respiration, and practical instruction in anatomy and physiology will be carried on in the laboratory, under the superintendence of Mr. Robertson, Mr. Jackson, and Mr. Poulton. Mr. Barclay Thompson will lecture on the Anatomy of the Amphibia, at the Museum. At Christchurch Mr. Vernon Harcourt will give a course of lectures on the Elements of Chemistry, and Mr. R. E. Baynes will give a course on Mechanics.

At Magdalen College Laboratory Dr. Pike will lecture on Chemistry, and Mr. Yule and Mr. Chapman on Biology.

Exeter College has lost the valuable services of Prof. Lankester. Mr. Lewis Morgan, formerly house surgeon at the Radcliffe Infirmary, will carry on instruction in the biological laboratory of the College.

In the month of November there will be an election at Balliol College to a scholarship on the foundation of Miss Hannah Brakenbury, "For the Encouragement of the Study of Natural Science," worth 80*l*. a year (55*l*. and tuition free), tenable during residence for four years. There is no limit of age, but members of the University must not have exceeded eight terms from

matriculation. The examination will begin on Friday, November 21, at 10 A.M. Papers will be set in (1) Mechanical Philosophy and Physics; (2) Chemistry; (3) Physiology. Candidates are not expected to offer more than two of these subjects. There will be a practical examination in one or more of the above subjects.

The Science Scholarships at Exeter College have been awarded to Mr. Alfred Evans, of Aberystwith College, and Mr. Percy Morton, of Manchester Grammar School. *Proxime* Mr. Makinder. The examination was held in Biology, Chemistry, and Physics. An extra scholarship was awarded this year on account of the proficiency of the candidates.

MR. J. J. HUMMEL, who has studied at the Polytechnic School at Zurich, and in the Chemical Laboratory at the Royal Institution, Manchester, under the late Mr. Crace Calvert, and has had wide experience in the art of dyeing at some of the best establishments in the kingdom, has been appointed to the post of instructor in the recently founded School of Dyeing, at the Yorkshire College.

MR. A. J. BENTLEY, M.A., Fielden Lecturer at Owens College, has been appointed Principal of Firth College, Sheffield; we are told there were "forty applications for the post." The college is to be opened next week by Prince Leopold.

ON Wednesday last week, the Rev. J. Percival, M.A., LL.D., who, from the establishment of Clifton College, and for seventeen years, was its popular head-master, and to whose exertions the high position that College has taken among the public schools of the country is mainly due, was presented by the citizens of Bristol with a very handsome and valuable service of plate on his leaving that city for Oxford, he having been elected to the office of Principal of Trinity College, in that University.

SCIENTIFIC SERIALS

Reale Istituto Lombardo di Scienze e Lettere, Rendiconti, vol. xii. fasc. xvi.—Periodical variations of tension of atmospheric aqueous vapour and comparative humidity in the climate of Milan, deduced from thirty years' observations at the Brera Observatory, by Signor Schiaparelli.—Further studies on the pelagic fauna of the Italian lakes, by Prof. Pavesi.

THE *Rivista Scientifico Industriale* (No. 16), contains the following papers:—On the power of dry and moist air of absorbing radiant heat, by Prof. Eugenio Cicognani.—On the diffused vapour in the interior of liquids, by Prof. Giovanni Cantoni.—On the thermal and galvanometric laws of electric sparks produced by complete, incomplete, and partial discharges of condensers, by Prof. Emilio Villari.—On the discovery of nitrous acid in the presence of nitric acid, by Dr. Augusto Piccini.—On a new balance spherometer, by Prof. Domenico Surdi.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, October 16.—M. Daubrée in the chair.—The following papers were read:—On the development of the perturbative function, &c. (continued), by M. Tisserand.—On artificial laurite and ferriferous platina, by MM. Sainte-Claire Deville and Debray. Laurite is got by heating to a bright red a mixture of ruthenium and iron pyrites. The sulphur from the pyrites combines with the ruthenium; the sulphide is dissolved in protosulphide of iron, and crystallises, on cooling, in regular octahedra, like natural laurite, or even in cubical crystals, easily separated from the iron by hydrochloric acid. A crystallised alloy of platina and iron is obtained by heating a mixture of platina and pyrites with borax, and treating with certain acids and potash.—Studies on the effects and the mode of action of substances employed in antiseptic dressings, by MM. Gosselin and Bergeron. The imputrescence of 1 gr. of blood is secured by a dose of 0·010 gr. to 0·015 gr. of carbolic acid; with smaller doses the putrefaction is retarded, but not prevented (at least if the dose be not gradually increased). As to the mode of action, the authors consider it is not exclusively by destruction of atmospheric germs (as Lister represents), but by the contact of the antiseptic producing coagulation of albumen. What the authors call the antiseptic alteration of the blood (by addition of a considerable proportion of carbolic acid or alcohol) consists (1) in thickening and yellowing (to the naked eye), and (2) in replacement of the globules by granular masses. This very rapidly-produced imputrescence could not be realised in wounds, the dose of antiseptic being too large; one can merely retard or diminish the putridity, and hope the blood will be absorbed before being altered in septicæmic degree.—On a sporadosideric meteorite that fell on January 31, 1879, at Becasse, Commune of Dun-le-Poelier (Indre), by M. Daubrée. The detonation was heard (about midday) at 20 km. distance. A sound as of a distant train preceded it, and it was followed by rumbling as of thunder. The meteorite (only one) was dug out from about 0·30 m. depth; it must have reached the ground almost vertically, while its trajectory seems to have been from south-south-east to north-north-west. It weighed 2·800 kg., and its form was roughly that of a pyramid with quadrangular base. It seemed to be chiefly formed of peridot and bisilicates (such as pyroxene or enstatite). The metallic grains consisted of nickelised iron, accompanied by tröilite. It belongs to the sub-group of oligosideres in the sporadosideric group.—On the mathematical theory of changes of brightness of double stars, by M. Gyldén.—The mildew, or false American oidium in the vineyards of France, by M. Planchon.—Extract of a letter to M. D'Abbadie, on the operations for junction of the triangulation of Algeria to that of Spain, by M. Perrier. These have been quite successful, and the meridian of France is now extended to the Sahara. The electric light was used in signalling.—On the synthesis of diphenylpropane, and on a new mode of formation of dibenzyl, by M. Silva.—Reaction of the cyanamide with the chlorhydrate of dimethylamine, by M. Tatarinoff.—On the cleistogamic state of *Pavonia hastata*, Cav., by M. Heckel. Physiologists who, like Pontedera and M. Bonnier, represent the *rôle* of nectaries to be that of organs of nutrition of embryos, have to give account of the fact that in the same cleistogamous plant, the close flowers, without nectar, are as fertile as the perfect flowers, sometimes more so, and sometimes fertile to the exclusion of these others.—Upper sands of Pierrefitte, near Etampes, by M. Meunier. He calls attention to some new species of molluscs represented there.—On the mineral associations contained in certain trachytes of the ravine of Riveau-Grand, in Mont Doré, by M. Gounard.—M. Chasles presented the first part of a memoir on the history of geodesy in Italy from the most ancient times to the middle of the ninteenth century, by Prof. Riccardi.—M. Larrey presented an English work by Mr. Longmore, on wounds by fire-arms.

THE INTRA-MERCURIAL PLANET QUESTION

IN No. 2253-54 of the *Astronomische Nachrichten*, Dr. C. H. F. Peters, the discoverer of so many minor planets, has "Some critical remarks on so-called intra-Mercurial planet observations," including the observations reported by Prof. Watson during the totality of the eclipse of July 29, 1878. Replies to these remarks have since appeared from Prof. Watson and also from Mr. Lewis Swift, of Rochester, New York, who, it will be remembered, also considered he had seen an object which could be no known star or planet. Prof. Peters enters upon other cases where intra-Mercurial bodies have been suspected, but we shall confine ourselves mainly here to his criticism of Prof. Watson's observations during the last eclipse. His object is to adduce evidence disproving Watson's conclusion that he had seen one, probably two unknown planets, and he grounds his argument chiefly upon the small size of the circles to which Watson trusted, and the fact that nearly on the parallel of his two objects a and b, and at an almost equal distance, a small one, in right ascension, were the stars θ and ζ Cancri. He states that the circles of wood with paper scales pasted on them, were only 5 and $4\frac{3}{4}$ inches respectively in diameter, and as Prof. Watson estimated the probable error of a position given by them at only five minutes, the space would measure on the circles only $\frac{1}{275}$ of an inch, and further he states that the wires which served as pointers "were so elastic as easily to give way several degrees under the touch by a pencil." So far, therefore, from accepting Watson's estimate of the precision of his readings, Prof. Peters thinks he does him no injustice in supposing that they were made "at the utmost to $\frac{1}{16}$ inch, corresponding to twenty minutes of arc upon his circles;" and in this case, the differences of a from θ Cancri, and of b from ζ Cancri, or + 2m. 55s. and + 3m. 23s. respectively, he believes may be explained by the errors in the markings or readings. It is also urged that the markings for the sun were made under circumstances less hurried than those for the suspected planets. Watson estimated the objects at the time of 4 and $4\frac{1}{2}$ magnitude, and, remarking that absolute magnitude must be quite uncertain under such conditions, Peters points out that the difference of brightness corresponds pretty nearly with that given by Argelander, Heis, and others between ζ and θ Cancri; and he adds, "it is, therefore, quite apparent to every unbiassed mind that Watson observed θ and ζ Cancri, nothing else." It should be added that Prof. Peters attempts to explain the ruddiness of the object near θ,—"If the sand ledge, under the lee of which the telescope was standing had nothing to do with it;" the observation, perhaps, teaches that the corona possesses the property of less absorbing the red rays, and may, therefore, be of some value. It seems also, in his view, that the corona gives a disk to the stars, or calms down the radiations to a kind of spurious disk, as a slight fog does; and as he does not admit that the power employed would show a real disk, we are to assume this was the case during Prof. Watson's observations. With regard to Mr. Swift's observations, it is represented that his successive publications offer so singular a gradation in the statements as to unfit them to be the subject of a scientific discussion.

As we have stated, Prof. Watson has replied to the criticisms which the Clinton astronomer has published to "make evident beyond cavil how erroneous the conclusion too rashly rushed at by the observers." He protests against mis-statement of the facts connected with his observations, remarking that it appears to him "the grossest of unfairness to attempt to discredit an observation made by an experienced observer by deliberately misrepresenting the circumstances of the observations." So far from the pointers of his circles bending under the touch by a pencil, they were made of unannealed brass wire one-eighth of an inch in thickness, not filed to a point, but to a *knife-edge*, placed vertical to the plane of the circle; they were quite rigid, and could not be disturbed in the least by the pencil when marking. The probable errors attributed to his readings Watson declares to be absurd, and says that any one interested may, by a few trials ascertain that by the method he adopted it is possible to measure without a greater probable error than 2′; the limit of 5′ which he gave was an outside one. Peters had urged that a practised observer would have compared the object a directly with θ Cancri, as the two would have been in the field together with the telescope employed, to which Prof. Watson replies, and with justice, that besides the want of time for such direct comparison, the method he was applying was different. If he had known that a new star would present itself near θ Cancri, he could have prepared himself for direct comparison; under the circumstances his plan of securing rapid indication of the position of any object that might be visible seems to have been as effective a one as could have been devised, and, as Dr. Draper termed it when it was explained to him the night before the eclipse, "a good dodge." Further, Watson observes that the assertion that his circles "were of wood, with paper scales pasted on to them, and wires serving as pointers," shows conclusively that Peters either did not yet understand his method, or that he was "purposely mis-stating the circumstances of his observations."

Finally, he makes what he terms these emphatic declarations:—"1. I observed, during the total eclipse of July 29, 1878, a new star between θ Cancri and the sun, and south of the sun, whose position and magnitude were as already published by me. 2. I observed another star, which I believe to be a new star, whose magnitude and position were as already published by me." Whether or not these objects were intra-Mercurial planets he does not positively assert, but he had the right to express the hones belief that they were. Watson adds that he "hopes ere long to give good reason for the faith that is in him," by which we understand him to imply that he has the intention to enter further upon the subject.

We will venture to say that the general feeling amongst astronomers when first reading Prof. Watson's announcement of his observations during the totality of the eclipse of 1878, of one, if not two, unknown objects, would be that a man of such known ability and experience as an observer, and so good a practical astronomer, as shown, amongst other proofs, by his able treatise on practical astronomy, would not risk his whole scientific reputation by putting forth such a statement to the world, unless he

was firmly convinced of its truth and felt able to substantiate it; otherwise the fact that there were two known stars, on the parallel or nearly so, and less than one degree west of the objects supposed to be new, would probably have been felt to be an almost fatal objection to the reality of the discovery. It must be remembered that Watson asserts he did see θ Cancri as well as the neighbouring object a; Peters objects—"not at the same time though"—an objection which Watson does not notice in his reply, but which will be easily removed by him; it might perhaps be rather gathered, that if the objects were not in the field together, he satisfied himself of their distinctness.

Throughout Prof. Peters's criticisms, not only as regards the American astronomer's observations during the eclipse, but other reported observations of unknown bodies in transit over the sun's disk, there is evinced a certain *animus*, which might have been as well avoided, and there is a flippancy in his reference to Leverrier's labours on the theory of Mercury, which he hopes "will be investigated anew by a hand very favourably known in this field of research, and we may expect then to have the intra-Mercurial spectre put to rest definitively." Most astronomical readers will feel more respect for the opinion of our great physical astronomer, Prof. J. C. Adams, who, on presenting the gold medal of the Royal Astronomical Society to Leverrier in 1876, thus expresses himself as to the existence of intra-Mercurial matter, as indicated by the French astronomer's researches—"The theory of the planet has been established with so much care, and the transits of the planet across the sun's disk furnish such accurate observations, as to leave no doubt of the reality of the phenomenon in question; and the only way of accounting for it appears to be to suppose, with M. Leverrier, the existence of several minute planets, or of a certain quantity of diffused matter circulating about the sun within the orbit of Mercury."

It has been mentioned that Mr. Swift has also addressed a communication to the *Astronomische Nachrichten*, in consequence of Peters's criticism of the observations made during the eclipse. Mr. Swift notified, soon after the occurrence of that phenomenon that he had seen two reddish objects with sensible disks about 3° distant from the sun; their mutual distance he first stated to be twelve minutes of arc, subsequently correcting this estimate to seven or eight minutes, as it is given in a letter which he addressed to NATURE, vol. xviii. p. 539, but in the same letter, referring the position of one object to that of the other, which he believed to be θ Cancri, by means of the place of the star given by the Astronomer-Royal in a communication to this journal, he assigned a position which, as we pointed out (vol. xviii. p. 569), would locate the supposed planet at a distance of thirty minutes from the star, instead of seven or eight minutes. He now writes that the difference of declination (? right ascension) shown by his own and Watson's observations, had been "a source of solicitude," as he could see no way to harmonise them "till NATURE pointed out the error of reducing the eight minutes of arc to time, saying it was but 32s. instead of 2m. This changed the whole complexion of the matter. The scales immediately fell from my eyes, and for the first time I was able to see my way clearly through the difficulty with which it had so long been enshrouded." We should have been glad if we could explain in what manner the sudden illumination consequent upon our remarks reconciles the distances in question, and so clear the way for accepting Mr. Swift's observation as confirmatory of that of Prof. Watson. He tells us that he has been an observer of the heavens for twenty-two years, and we know that he has been the first discoverer of several comets, and have no intention to depreciate his claim to credence on any astronomical question, but it has naturally happened that the different statements and the hesitation felt as to the distance of the objects he observed has detracted from the importance which would otherwise have attached to his experiences during the eclipse.

AUSTRALASIA

Australasia. Edited and Extended by A. R. Wallace. With Ethnological Appendix by A. H. Keane, M.A. (London: Stanford, 1879.)

THIS stout octavo volume is one of the series entitled "Stanford's Compendium of Geography and Travel," based on Hellwald's "Die Erde und ihre Völker." Mr. Wallace tells us, however, in the preface that he has been able to utilise comparatively little of the translation of Hellwald's work, so that it forms little more than one-tenth part of the present volume.

The term Australasia is taken in a very wide sense to include the entire East Indies and the Philippines, New Guinea and Australia, and all the islands of the Pacific, even to Easter Island. The region extends thus around much more than one-third the circumference of the globe.

The book commences with a short general account of the main geographical and biological features of the area and then treats of its various subdivisions separately. The author divides his Australasia into six principal regions, viz., Australia, Malaysia, Melanesia, Polynesia, Micronesia, and New Zealand. He commences with a very interesting summary of the principal physical features and climatic conditions of Australia.

Australia with Tasmania is only a little less in area than Europe. Yet its highest mountain, Mount Kosciusko, is only 7,308 feet in height. Its greatest river, the Murray, has a basin the area of which is about equal to that of the Dnieper. The hottest climate in the world probably occurs in the desert interior of Australia. Capt. Sturt hung a thermometer on a tree shaded both from sun and wind. It was graduated to 127° F., yet so great was the heat of the air that the mercury rose till it burst the tube, and the temperature must thus have been at least 128° F., apparently the highest ever recorded in any part of the world. For three months Capt. Sturt found the mean temperature to be over 101° F. in the shade. Nevertheless in the southern mountains and tablelands three feet of snow sometimes falls in a day; in 1876 a man was lost in the snow on the borders of New South Wales. Snowstorms have been known to last three weeks, the snow lying from 4 to 15 feet in depth and burying the cattle. Forty miles of the railway from Sydney to Bathurst have been seen covered continuously with snow. Australia is the land of drought and flood. The annual rainfall at Sydney has varied from 22 to 82 inches. Lake George, near Goulburn, was, in 1824, 20 miles long and 8 miles broad.

It gradually shrank till, in 1837, it became quite dry, and its bottom was converted into a grassy plain. In 1865 it was a lake again, 17 feet deep; two years later, only 2 feet deep; and in 1876 it was 20 feet in depth.

The account of the flora of Australia Mr. Wallace takes from Sir Joseph Hooker's exhaustive essay. In the description of the zoology he makes a curious slip in stating (p. 57) that the Banded Ant-eater (*Myrmecobius*) has a greater number of teeth (fifty-two) than any known quadruped. He quite forgets the big Armadillo (*Priodonta*), which has nearly twice as many, to say nothing of the crocodiles. It is also hardly correct to say that the Monotremes have no teeth.

After an interesting summary of the geological features of the country and of the mode of occurrence of gold, an account of the natives ensues. It contains interesting information, but seems hardly precise enough, those points in culture in which Australians differ from all other races being hardly brought out with sufficient distinctness. Such a statement as "that the life of the Australian native is one of abundance and privation, idleness and activity," might be made of all savages in the world. It is hardly accurate to describe a boomerang as "about three feet long," boomerangs being used of very various sizes, and many of the Western Australian and Queensland weapons being of about only a foot and a half in length. Again, why denote the spear thrown by means of the throwing-stick as "about ten feet long"? The spears thus used are of most various lengths, and some employed at Cape York are not more than five feet long at the most. Again, the throwing-stick is not always "a straight flat stick," but ranges through many forms, one being oval and shield-like.

Throughout the book the implements and weapons of natives are described in a slipshod and insufficient manner, as where the Papuans are stated to possess "Knives and axes, both formed of sharply chipped flints, resembling those of the stone age found in Europe." We believe that no flint implement has ever been found in New Guinea. The Papuans have knives of obsidian, and stone-headed axes and adzes, but the blades of these latter are not made of flint, but of jade or greenstone, or some similar material, and are not chipped to an edge, but invariably ground smooth all over. The only recent savages, apparently, who employ unground stone axe blades are the Australians, and very many of their blades are wholly or partially ground. Again, the canoes of the Admiralty Islanders are described as "formed of a hollowed tree with the sides raised by a plank and fitted with an outrigger." Such a description might apply to numberless other canoes occurring in Mr. Wallace's region of Australasia. The peculiar interest in the Admiralty Island canoe lies in its having two outriggers, or rather, an inclined balance platform opposite to the ordinary outrigger.

The real interest in the study of savage weapons and implements lies in the differences to be observed in the form and structure of the contrivances used by each race. The implements manufactured are often as characteristic of the race as is its language. They have certain general family resemblances in their form to those employed by nearly allied races and certain special peculiarities, some, like words from a neighbouring language, have been imported, and may or may not have undergone subsequent modification, others are absolutely peculiar and characteristic. When taken as a whole they are as important for the elucidation of the past history, and the determination of the affinities of the races of men as are language, or even to some extent physical characteristics. A description of the implements used by a race in order to be of real value and interest, should point out what particular implements are peculiar to the race, and in what their peculiarity consists, and what are common to the race and its immediate allies. A mere catalogue of implements, ornaments, and weapons given without detail or explanation is valueless.

The several colonies of Australia are treated of in detail in the present work. In the account of New South Wales Port Jackson is, as usual, vaunted as one of the safest, deepest, and finest in the world, but it should always be remembered that though it is very pretty and very deep inside, its entrance channel is not deep enough to admit a first-rate ironclad, and that men-of-war sometimes suffer from lack of shelter in Farm Cove, and drag their anchors.

By an unfortunate slip, under the description of Queensland, *palms* of the genera *Cycas*, Areca, &c., are spoken of, a mistake the more misleading to unbotanical readers because Cycads are not unlike palms in outward appearance.

In the account of the Malay Archipelago which follows in the description of the Sulu Islands and their notorious pirates, it should have been mentioned that the Sultan of the islands has at last submitted to the Spanish rule on receipt of a sum of money. An arrangement to that effect was made about a year ago, and an agreement signed at Manila.

Dr. Horsfield's interesting account of the Tenger Mountain, the great volcano of Java, is quoted at some length in the account of that island. The crater of the mountain is said to "exceed perhaps in size every other in the globe;" yet it is only four miles and a half in larger diameter and three and a half in smaller, whilst the great crater of Haleahala, in the Sandwich Islands, really the largest in the world, is twice as big, measuring over twenty miles in circumference. Curiously enough, no mention whatever is made in the book of this wonderful crater, nor of the island of Maui, in which it occurs, in the very meagre account of the Sandwich Islands, in the part of the work which treats of Polynesia.

The first portion of the work, which treats of Australia and the Malay Archipelago, is by far the best. The account of Polynesia generally which follows is most indifferent, as might be expected from the astonishing fact that no reference whatever is made to the two most important works on the subject, viz., Meinicke's "Inseln des Stillen Oceans," and Gerland's stout volume in Waitz's "Anthropologie." If good use had only been made of these works the result would have been far more complete and trustworthy; but a translation of Meinicke's work would have been better still.

The figure given as that of a native of Fiji is very unfortunate, since the face is represented as elaborately tattooed, whereas tattooing on the face is excessively rare in Fiji, and tattooing on men at all rarer still. It is not correct, however, to state that "in Fiji the women only are

tattooed" (p. 488). Good photographs of Fijians are so common now and so easily procured that it is a great pity one of these was not copied for the book.

With regard to cannibalism in Fiji the statement is made that perhaps nowhere in the world has human life been so recklessly destroyed or cannibalism been reduced to such a system as here, and the putting of twenty bodies into the ovens at one feast is described as most astonishing; yet the New Zealanders, who are necessarily also treated of in this book, were quite as systematic in their cannibalism and far more profuse, as many as 1,000 prisoners having been slaughtered and put in the ovens at one time by them after a successful battle.

In the general account of Polynesia the Polynesians are said to have no bows and arrows. This is a mistake; both Hawaiians and Tahitians had bows and arrows, as we know from the writings of Cook and Ellis, though they did not use these weapons for war purposes. Ellis's account of the sacred archery of Huahine, where the ancient archery ground was close to his residence, is most interesting and full of detail. Bows and arrows were also used in Tonga and Samoa. To say of Polynesians generally that "all the men are tattooed from the navel to the thigh" (p. 495) is strangely misleading, since it would appear from it that all Polynesians were alike in their customs of tattooing, whereas, as is well known, the greatest differences occurred in this matter, and the description quoted would apply almost solely to the Samoans and Tongans, though there was a slight difference even between these two races in the matter.

Still more misleading is the statement that the Polynesians "have none of the savage thirst for blood of the Fijians," and that "their ceremonies are polluted by no human sacrifices; cannibalism with them has never become a habit." To such an absurd conclusion regarding Polynesians is the author led by his having separated off the New Zealanders from the Polynesians into a separate chapter. He treats of the New Zealanders correctly later on as "Brown Polynesians," like those he is describing as above. But cannibalism was not confined to New Zealanders amongst the Polynesians, but widely spread amongst all, occurring in the Hervey Islands, Paumotu, Tahiti, the Sandwich Islands, the Marquesas, and elsewhere. Human sacrifices were also regular institutions in all the islands, for example, in Hawaii, Tahiti, and the Marquesas, and in the latter group men killed their wives and children, and their aged parents for eating. In the time of Cook cannibalism was very much on the decline in Samoa and the Sandwich Islands, and had ceased in Tahiti, but evidence of its former more common occurrence was preserved in popular legends, proverbs, and traditions, and in some curious ceremonial customs. In the Paumotu Islands it long remained a regular institution, and Ellis saw a captive child there given a piece of its own father's body to eat. But what can be expected from a work on Polynesia which is without a reference to Ellis's "Researches," and in which Tonga is treated of without a reference to Mariner, or even mention of his name?

In the account of Tahiti Mr. Wallace becomes quite poetical, but stumbles rather in his zoology in consequence; he writes:—"The wayfarer's ears are ravished by the music of various songsters arrayed in the brilliant plumage of the tropics." There is, indeed, one thrush-like bird (*Tatare longirostris*) in Tahiti which sings sweetly, especially in the higher mountain regions, but it is no more brilliantly coloured than are singing birds usually elsewhere, in fact as dull as most songsters in appearance. There are brightly-coloured birds amongst the meagre list of about twenty-six land-birds of the island, but these are fruit-pigeons, parrots, and king-fishers. Though the great denudation of the surface of Tahiti is referred to the extraordinary steep and narrow ridges thus formed, and which are such characteristic features of its surface are not mentioned. The following passage will be most amusing to any one who knows anything of Tahiti. "At present we must visit the interior in order to see in their original forms the seductive dances of the native women, gaily decked with flowers." In fact the interior of the island is mountainous throughout, and uninhabited. The natives know very little about it, and it is quite a feat for a European to make his way across it. The dances in question take place usually close to the sea-shore, when they do occur now, and a large bribe administered to one of the native washermen will generally set one on foot, these worthies ministering to the pleasures of tourists as well as washing their clothes.

In the account of Rapanui (Easter Island), the conclusion "that at present the island is the great mystery of the Pacific, and that the more we know of its antiquities, the less we are able to understand them," is unworthy of the present state of ethnological knowledge. Too much mystery is made about the stone images of Rapanui, and in his "Tropical Nature," p. 291, Mr. Wallace, following Mr. A. Mott, actually brings these images forward as one of the proofs of a former general advanced intellectual condition of mankind as opposed to the accepted scientific position that primitive man was savage.

Earlier in the book he similarly cites the big upright stones found by Brenchley in Tongatabu as proving the existence of a preceding more highly civilised race. It is misleading to term these Rapanui remains "prehistoric," as implying that they have any vast antiquity. There is no reason to doubt that the present islanders, who are by language of Raratongan origin and by tradition come from Rapa Island, are the direct descendants of those who set up the images and constructed the underground houses for their chiefs. The wooden tablets with hieroglyphic inscriptions, and wooden gods cannot be very old, and the same characters are inscribed on the backs of the stone images, as may be seen in the case of the one in the British Museum as are cut on the slabs. The stone crowns on the images' heads merely represent the feather head-dresses worn by the chiefs. Similar blocks were appended to the heads of some of the Sandwich Islands gods and to the stone gods of the Marquesas Islands. The stone images are in point of artistic execution miserably low, and their workmanship does not go to prove that any high development of culture existed here in former times, though the absence of artistic merit would hardly be allowed to prove the opposite condition as to general culture by such authorities at least as those who ately erected a row of stone heads very little more advanced in their resemblance to the human form in front of the Sheldonian Theatre at Oxford. The Rapanui stone images resemble the wooden ones of the island in features

in many points, and there is also a resemblance in form between these stone images and the smaller ones of other Polynesian islanders. Mr. Wallace makes all the mystery out of the fact that the present islanders know nothing of the images, but savages quickly forget. The very name of the image platform Moai, as Meinicke remarks, seems to be the same as that of the old Tahitian chief's burial places, "Marae," Hawaiian, "Morai."

The account of the Sandwich Islands is very short and contains several errors. Mauna Kea, the highest of the three volcanic mountains of the Island of Hawaii, is described as an active volcano instead of as extinct. Kilauea should hardly be described as the most remarkable "*burning mountain*" in the world. It is really a lateral crater only on the side of Mauna Loa, the terminal crater of which is far more remarkable when in eruption than that of Kilauea. It is rather stretching a point to speak of the crater of Kilauea as a *fathomless* oval abyss, for tourists from the hotel on its brink usually walk nearly all over its bottom on a floor of hard lava, and the descent to the bottom is no great one. The figure given in the text as representing *Kilauea volcano* apparently is taken from a sketch of one of the ponds of fluid lava usually present at one end of the bottom of the crater.

No account is given of the ethnological characteristics of the Hawaiians, and nothing of the importance of the Chinese settlers in the group, nor of that of the developing half-caste population. The establishment at Honolulu of the hostile Church of England Mission is spoken of with the warmest approbation, whereas most unprejudiced persons regard it as an unmixed evil that the natives who have been Congregationalists for nearly eighty years, should be interfered with by a different Protestant sect.

In the account of New Zealand (p. 564) the possibility is suggested of a former land connection having existed between the Kermadecs and New Zealand. Such a connection would explain well some of the peculiarities of the flora, especially of the ferns of the Kermadec Islands, but unfortunately a depth of 2,000 fathoms was found by the *Gazelle* to exist between the two places, and the connection cannot therefore have existed. It is surprising that Mr. Wallace speaks of the Kermadecs as interesting *only* because they form a stepping-stone to Tongatabu to assist in the migration of Polynesians: he forgets entirely the interest of their flora as described by Sir J. D. Hooker.

The work concludes with an essay by Mr. A. H. Keane, on the Philology and Ethnology of the Inter-Oceanic Races. A long and very useful catalogue is given of the inter-oceanic races and languages, and of their very numerous and puzzling native names, with good references appended. It is very voluminous, and we were astonished to light upon an omission in so complete a catalogue. It was that of the Lutaos, the native name for the Sulu pirate race.

On the whole, it is to be regretted that Mr. Wallace has not studied other German sources of information than Hellwald's work with care. The fact is it is too much to undertake to describe Polynesia together with the Malay Archipelago, Melanesia, and Micronesia, all in one volume, and the result has been that Polynesia has suffered in treatment. The most striking defect in the book, however, lies in the meagreness of the references, the catalogue of which, at the beginning of the book is very small and contains almost solely English books. There is no reference to Finsch's work on New Guinea ("Neu Guinea und seine Bewohner") nor to the Goddefroys' publications; and with the splendid bibliography of Meinicke's and Gerland's works before us, the neglect of the literary side of the subject is most irritating; but Mr. Wallace, as most working zoologists know to their cost, neglected also to supply adequate references in his work on the "Distribution of Animals," and thus reduced the value of the work by at least one-half. If any one wishes to obtain a concise scientific account of any of the Polynesian or Melanesian islands, and references which will when consulted put them in possession of all the information to be obtained, they should read Meinicke's book, and not "Australasia."

In conclusion, our readers may be reminded that very much yet remains to be done in the exploration of the Australasian region, and most interesting results may be expected when the snow-clad Charles Louis Mountains of New Guinea, possibly 18,000 feet in height, shall have been climbed by the naturalist, and such other hitherto unvisited regions as the island of Timor Laut and the great central mountain of Ceram Nusa Heli, said to be near 10,000 feet in height, from which Mr. Wallace, who has best right to judge, expects great things.

OUR BOOK SHELF

Geological Glossary for the Use of Students. By the late Thomas Oldham, LL.D., F.R.S. Edited by R. D. Oldham. Pp. 62. (London: E. Stanford, 1879.)

THIS is a posthumous work by the late lamented Superintendent of the Geological Survey of India. In a modest preface the author's son, who edits the work, explains that its object is to furnish a companion to the recognised geological text-books by including such terms only as are likely to be met with by beginners, and explaining them in the most concise and simple manner possible.

The definitions given in the book are always brief and to the point, but in a few cases in the attempt to be concise, the author has scarcely succeeded in making his explanations sufficiently clear for a student. We notice that the common mistake is made of confounding together the German words *Keuper* and *Kupfer*. The book is, however, very carefully prepared and edited, the arrangement and typography leave nothing to be desired, and we have no doubt that it will prove of the greatest service to the class of students for whom it is designed.

Ueber die Tektonik der Vulcane von Böhmen. Von Dr. Ed. Reyer. (Vienna: Alfred Hölder, 1879.)

IN this memoir Dr. Reyer shows that the Schlossberg of Teplitz is really a volcanic cone which has been produced by the successive and continued out-wellings of masses of phonolite lava from a volcanic centre. This he is able to prove by a study of the position of the great divisional planes which intersect the mass. The diagram of the internal structure of the mass of volcanic material, which he is thus enabled to construct, shows the most complete agreement with that of the plaster models which Dr. Reyer has described in an earlier paper on the subject. The author also adds some interesting information upon the old denuded volcano of Klein Preisen, and the whole paper forms a valuable and suggestive contribution to our knowledge of volcanoes, which is well worthy of attentive study. J. W. J.

An Essay on Spiritual Evolution considered in its Bearing upon Modern Spiritualism, Science, and Religion. By J. P. B. (Trübner and Co., 1879.)

THIS is an essay of 150 pages by a thoroughgoing "spiritualist," according to the most "modern" signification of the term. As such it is not a book very easy to review in the pages of a periodical devoted to the consideration of modern science. Whether or not spiritualism has any basis of truth, it is certain that a genuine belief, if not in spiritual agency, at least in the occurrence of certain weird and inexplicable phenomena, has of late years spread with extraordinary rapidity, and now includes among its avowed supporters some distinguished scientific men of the day. The estimate that a reader will form concerning the merits of the essay will depend chiefly on his attitude of mind concerning its subject. For "J. P. B." assumes the genuineness of so-called spiritual manifestations, his thesis being that granting a future state and the reality of spiritual communications, these communications invariably teach a doctrine which is in harmony with—or rather analogous to—the doctrine of organic evolution; they teach that gradual development is the law of spiritual life after death as it is the law of bodily life before death. We feel that our function as reviewers ends, when we say that in all his statements of and references to the facts of physical science the essayist is accurate. These statements and references appear, indeed, to us more numerous than the treatment of his subject requires; but if so they at all events serve to show, what perhaps they are intended to show, that "J. P. B." is an intelligent man, who, while prosecuting his spiritual studies—whether in the body or out of the body we do not know—still keeps his eyes open to what is going on in the lower world around him.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Sun-Spots in Earnest

AFTER three days of total cloud, but after months and months of general watching for sun-spots, and seeing either nothing at all, or only the smallest possible points visible in my household instrument, merely a little picture-forming model of an equatorial by the ancient Ramsden—I could hardly believe my eyes this (Saturday) morning on beholding, even in spite of driving clouds, haze, and smoke, three comparatively enormous sun-spots besides strings of smaller ones connecting them. The group was situated not in the sun's northern, as all the other little points had been, but in its southern, tropic; not just coming into view at the following limb after unknown periods of concealed growth on the other side of the solar orb, but only a day or two past the very middle meridian of its earthward side.

Hence these gigantic spots may have burst, exploded forth, only a day or two ago, and just when their locality was turned towards the earth; and it is indeed greatly to be hoped that some regular and accomplished solar observer in one of the astro-physical observatories may have been lucky enough to have positively seized and photographed this, for years past, most unequalled phenomenon both in its suddenness and immense extent. The energy too which must have presided at their birth, was borne continued witness to this day by rapid changes in the configuration of the spots; and certainly, take them all in all, the long quiescent period of the sun's internal heat-forces seems now to be fairly over, and the wondrous orb, on whose influences we all physically exist, is embarked on a new cycle of radiant activity. PIAZZI SMYTH

15, Royal Terrace, Edinburgh, October 18

Climatic Effects of the Present Eccentricity

I HAVE just read the Rev. O. Fisher's letter (vol. xx. p. 577) asking for an explanation of the reason why the January temperature at the equator, when the earth is in perihelion, is not much higher than in July when in aphelion. The temperature to which Mr. Fisher refers is the ordinary temperature as indicated by the shaded thermometer, which, of course, is simply the temperature of the air. I do not think it is difficult to explain why the *air* at the equator in January cannot be much hotter than in July.

If it can be shown from observation that the black bulb thermometer which indicates, not the temperature of the air, but the direct heat of the sun does not stand higher at the equator in January than in July there would certainly be a difficulty, if the temperature of space be as low as $-239°$ F. It would be desirable to know if such is actually the case. Perhaps some of your readers might be able to afford some information on this point, which seems to have been overlooked by meteorologists.

In a future letter I shall give what appears to me to be the reason why the air at the equator is not hotter in January than in July. JAMES CROLL

Greenwich Meteorological Observations

WITH reference to Mr. Ellis's letter in NATURE, vol. xx. p. 576, it may be enough to point out that, as Table 77 gives only the mean temperature of each day and month of the year for the whole period of the twenty years' observations, we must look elsewhere for the mean temperatures of the months of each successive year; and that this information is not furnished by Table 52, seeing that the means of that table have been prepared without correction for omitted days. Could Table 125 have been accepted as giving accurate mean temperatures this information would have been before us; but as matters stand a table showing the mean monthly and annual temperatures of Greenwich during each of these twenty years remains still to be constructed. An explanation as to how the daily mean values for those days on which no photographic value was available, were obtained in constructing Table 77, and a statement of the daily inequality of temperature of the underground apartment in which the photographic barometer is placed, would enable meteorologists to value even more exactly the highly important results of the Greenwich Meteorological Observations.

ALEXANDER BUCHAN

Rag-Bushes

CONSUL LAYARD has given a remarkable instance of this form of fetishi m, practised by the Cingalese, near Jaffna, as illustrating the paper read by Mr. Walhouse at the Anthropological Institute, April 8, 1879. When passing through the Betsileo forest country many years ago we came frequently on somewhat analogous monuments.

"Often on the summit of some of the steepest ascents we found huge piles of branches, twigs, bits of cloth, &c., the thank-offerings of passing travellers for having reached thus far on their journey and surmounted the hill" ("Madagascar and the Malagasy," p. 32, Lieut. Oliver, R.A.). According to Mr. George A. Shaw, of the London Missionary Society, in the last number of the *Antananarivo Annual*, "These heaps are called *tatào*, and have been added to at various times by people carrying firewood or dried grass, &c., to market. They throw on a piece 'for luck,' repeating a form of words, signifying, that if they are fortunate in getting a good price for their goods, when they return they will add another piece to help the *tatào* to grow large. Men driving cattle, or sheep, or pigs, throw on stones with the same speech, often spoken mentally only."

The Rev. R. Batchelor, S.P.G., who accompanied Bishop Kestell-Cornish to the Antankarana country also mentions that when, in trying to knock down the seeds, he threw pieces of wood and stone up at a fan palm, he was requested to desist by one of the villagers "as the tree was *Zànahàry, i.e.*, God, adding at the same time, that a man who had dared to cut the trunk with a knife had been killed the same day by Zànahàry's anger." But should I find an intelligent Malagasy battering one of my pet conifers to obtain the cones I should also remonstrate, and unless he was a good linguist he would assuredly believe that I considered my specimen-plants *sacred, i.e.*, from stones and sticks. A far better example is that recorded by the Rev. J. Richardson, Head Master of the London M.S. Normal School at Antananarivo, as occurring at Vólotaràỳ, in the Bara country,

en route to St. Augustine's Bay: "As we drew near to Vólotaráy River and town, I noticed a fetish tamarind tree that calls for a little notice. The tree itself is one of the largest in the neighbourhood, and is a notable object when viewed at a distance. The whole aspect of it strikes the stranger at once; its bell-shaped crown, and its branches reaching to the ground being particularly noticeable. I found on close examination, that its trunk divides into two a few feet from the ground; the diameter of its shade is 81 feet, and its branches torch the ground all round the circle. Through its branches there are other trees growing, seeking the sun through its dense foliage; some of these trees are quite a foot in circumference, and there are creepers clinging to them. So that the tree is a miniature forest in itself. The cool shade beneath its branches was most welcome. About a foot from the double trunk a trench encircling the tree has been cut in the sandy soil. This trench, or gutter, is about six inches deep, a foot broad, and is swept most scrupulously clean by some one, and the ridges on each side are patted down so that the sand may not fall into the gutter.

"On the raised earth between the gutter and the trunk of the tree are laid small baskets, mats, fan-palm leaves, locks of hair, &c., &c., and on the surrounding branches similar articles are hung, evidently placed there in making a vow, or as a thank-offering for some benefit, but what I could not tell. The tree is some hundred yards from the town, and when we arrived and inquired about it, no one knew (?) anything of there being such a tree. . . .

"The tamarind trees are apparently held in reverence by the Tanòsy as well as by the Bara, and at some little distance from Rabòdo's compound, at Kiliarivo, there is a very fine specimen of a fetish tree, to which they gave the name of Zànahàry. It is surrounded by a very high fence of prickly pear, and the narrow passage to it had been made impassable by cutting from the fence portions of the thorns and strewing them across the path."

Following is the translation by Mr. Jas. Sibree, jun., L.M.S., from an account by a Hova officer, who commanded an expedition against the Sàkalàvas in 1873:—"Before coming to this village we saw other things of a similar kind, for there is a certain tree they call 'Botóna,'[1] and in this tree there is some part considered as specially belonging to God. So they put on it a small mat about a hand-breadth in width, and they take long dry grass and twist it together, and hanging an ox-skull to the tree, they colour the tree with lines of charcoal and white clay and some yellow substance resembling turmeric, and then pray and render adoration before it. And many are the charms they place on the tree, fastening them to it, and every charm has a name peculiar to it. These are some of them: one is called 'Road-stopper,' another 'Raising up at a distance,' and another 'God's banner.' . . . In another direction which we took we saw some villages with a great many trees growing round them, and the largest tree which grew near the gate had a figure of a woman fixed to it, and ornamented with charms. We asked the meaning of this, and were told, This is the tree of adulterous desires, for here those pray who want women or are about to marry."

I may add that Mr. Richardson, mentioned above, with his wife and family, have lately landed in England, per steamer *Agra*, from Madagascar. It is greatly to be hoped that the reverend missionary will give a detailed account of his adventurous journey to the south-west coast. S. P. O.

[1] Botóna, or Bontóna is the Baobab, or monkey-bread tree (*Adansonia digitata*).

The Theory of Hailstorms

Would you kindly allow me the space in the columns of your valuable journal to make a few remarks on this subject? Before proceeding, I would like to mention three results of observations on hailstorms in general. It has been observed (1) that they move over the country in sharply-defined bands; (2) that these long bands have their origin or source in mountainous regions; and (3) that the air, previous to the occurrence of the storm is frequently hot and sultry, and that when it has passed, the wind feels sharp and cold.

Theorists admit that the generation of hail seems always to depend on some very sudden introduction of an extremely cold current of air into the bosom of a quiescent, nearly saturated mass. Now, bearing in mind the above-mentioned facts, does it not seem probable, or at least possible, that hailstorms may be caused by a current of wind which has been forced over snow-covered mountains, and thus rendered extremely cold, descending into the warm plains beneath, and forcing the hot and saturated air resting thereon, into the higher regions of the atmosphere, where the moisture would become congealed into a cloud of ice particles, the condition required for the beautiful theory of the formation of hailstones of Prof. Osborne Reynolds? This would account for the great frequency of hailstorms in Southern France, which country is subject to the influence of both the Alps and the Pyrenees. The above conditions, viz., snow-covered mountains and warm plains, could only occur in this country in winter and spring, and it is found that the greatest proportion of our hailstorms are experienced in these seasons.

I do not here enter into details. Should the theory be considered admissible, I hope on some future occasion to give the results of a full investigation of the subject, with my arguments in support of the foregoing opinion. J. A. B. Oliver

Springburn, near Glasgow, September 29

Underground Tides

Mention is made in Nature, vol. xx. p. 401, of a spring in the Dux coal mines, Bohemia, exhibiting ebb and flow similar to tides. May not this be due to a subterranean syphon, acting precisely as a Field's flushing tank would in a house drainage system Mention of such springs is made in Silliman's "Principles of Physics." We have in our neighbourhood not far from the Mammoth Cave a surface pool about 50 feet in diameter exhibiting this apparent tidal action. The pool is situated in the cavernous limestone country that forms such a large portion of our state, and is only a few hundred yards from Green River, whose peculiarly tinted waters it closely resembles. There is but little doubt that the river furnishes it with water until a level is reached, bringing one of the numerous underground conduits in the limestone into action, when the pool ebbs.

Louisville, Ky., U.S.A., October 9 Morris B. Belknap

The Uses of Tails

A very important function of the tail of the yak, cat, squirrel, and many other animals, to which I drew attention some years ago, has escaped the notice of Prof. Mivart. It is that the bushy tails of these animals serve a very important function in preserving their body-heat during their nightly and their wintry sleep. In cold weather animals with bushy tails will be found lying curled up with their tails laid carefully over their feet like a rug, and with their noses buried in the fur of the tail, which is thus used exactly in the same way and for the same purpose as we use respirators.

I have a Manx tailless cat, who cannot, of course, carry on this function, but he makes a very good substitute for it by using the back of one of my other cats. When he cannot be so accommodated, he sleeps with his hands crossed over his face, "just like a Christian," as my cook says. Lawson Tait

OUR ASTRONOMICAL COLUMN

Binary Stars.—Dr. Doberck, of Col. Cooper's Observatory, Markree Castle, Sligo, continues his interesting investigations on the orbits of the revolving double stars, and now gives a first approximation to the elements of O.Σ. 298, which, since the first measures by Mädler in 1843, has advanced upwards of 135°, the distance, meanwhile, diminishing from about $1\frac{1}{4}''$ to $0''\cdot3$; the passage of the periastre is fixed to 1881·76, and the period of revolution assigned is 68·8 years. It may soon be possible to infer approximately the elements of several other binaries as μ Herculis, O.Σ. 518, the duplicity of which was detected by Herschel in 1783, and which has special claims to the attention of the observer, from its evident physical connection with the rapidly-moving star 40 Eridani (one, by the way, that Mr. Gill intends to attack for parallax), and No. 298 of M. Otto Struve's catalogue. In a new orbit of Σ 3062, by Dr. Doberck, the period is 102·94 years; periastre 1835·5.

The Satellites of Mars.—Mr. Marth has published data for facilitating the calculation of the positions of *Deimos* and *Phobos* (*Ast. Nach.*, No. 2280), including for

the former satellite the partial effect of perturbation, and leaving the remainder of the process in as simple a form as practicable. He remarks that if the satellites cannot be followed up to December 15, there is little chance of their being seen in 1881, except, perhaps, under greatly improved atmospheric conditions, and we may then have to wait for further observations until the very favourable opposition of 1892; a similar opinion has been expressed by Prof. Newcomb; hence the greater necessity for reliable measures of the satellites during the present opposition. We have not yet heard of any observation of *Phobos* in this country, but Mr. Common continues measures of the position of *Deimos*, which is not far from that given by Hall's elements.

THE MINOR PLANET, PANDORA.—Dr. Axel-Möller, of Lund, has communicated to the Academy at Stockholm an exhaustive determination of the orbit of this small planet, which he appears to have taken under his special charge. It is founded upon the observations at the sixteen oppositions between 1858 and 1877, the perturbations of Mars, Jupiter, and Saturn being rigorously determined by Encke's method. The residual errors are smaller than in any like case we remember, except in Mr. Godward's investigation of the elements of Ceres in 1878, from a similar length of observation (fifteen oppositions) and refined calculation of the perturbations. Dr. Axel-Möller had presented an elaborate memoir on the absolute perturbations of *Pandora* to the Swedish Academy in 1877.

PALISA'S COMET.—Herr Zelbr, of Vienna, has published elements of this comet, which will be probably nearer the truth than any others that have appeared; they are founded on four days' observations between August 21 and September 12, and are as follow:—

Perihelion passage, 1879, October 4·60015 M.T. at Berlin.

	°	′	″	
Longitude of perihelion	202	27	15	Mean Equinox, 1879·0.
,, ascending node ...	87	7	30	
Inclination	77	6	12	
Log. perihelion distance	9·995932			

Motion—direct.

These elements give for Berlin midnight:—

	R.A. h. m. s.	Decl. ° ′
Oct. 23	15 36 56	+ 2 7·0
25	— 42 58	+ 0 24·4
27	— 48 50	− 1 15·2
29	15 54 32	2 51·8
31	16 0 6	4 25·3
Nov. 2	— 5 31	5 55·8

12	— 31 8	12 45·5
14	16 36 2	−13 59·4

On November 8 the intensity of light has the same value as on the day of discovery, August 21.

GEOGRAPHICAL NOTES

TWO members of the Greenland Scientific Expedition, viz., Lieut. Jenson and M. Kornerup, arrived back at Copenhagen on October 13 in the Greenland trading ship *Ceres*, which sailed from the colony of Egedesminde September 4. Lieut. R. Hammer left Egedesminde at the same time for the colony of Jacobshavn to take up his winter station there, in order to fulfil the special duties intrusted to him. M. Steenstrup takes up his winter station in the Umanak district, and it is intended that Steenstrup and Hammer shall meet next year, so that they may prosecute their researches together.

MÉNILIK, King of Shoa, has written a letter to the president of the Geographical Society of Paris in reference to the scientific mission which has been sent to Shoa by the Geographical Society of Rome and which has the protection of his government. But the King would like better to have to assist a French mission sent to him by the Geographical Society of Paris; consequently he desires the Society to fit out an expedition, promising them to employ all his power on their behalf. He complains bitterly against the Egyptian Government, which prevents Abyssinia from being placed in communication with European civilisation as it had been in former centuries. The letter is written in French and sent with an Abyssinian translation.

THE Grand Duke Nicholas of Russia has ordered M. Barante to translate into French his work "On the Canalisation of the Amu-Daria" and present it to the Paris Geographical Society. The work will be published *in extenso* in the Transactions of the Society.

A TELEGRAM received by the Russian Geographical Society communicates the following particulars as to the scientific expedition now exploring Tibet, under the leadership of Col. Prshevalski. On May 1 it was on the river Boolagan, having marched nearly 600 versts from Saizan, through Booluntokhoi, up the river Yrungo. The Colonel intended crossing the southern Altai Mountains by the shortest way to Barkool. All his companions were in good health, and success had attended all their efforts. Another telegram to the Russian General Staff, dated May 30, states that Col. Prshevalski had then accomplished a third part of the distance between Saizan and the Himalayas, reaching the town of Khani, whence he intended going to Shadsheoo and Paidan. Another Russian geographical expedition, it will be remembered, in three sections, is at present prosecuting researches east of the Caspian, though the same success does not seem to crown its labours. A letter reaching St. Petersburg by way of Orenburg says that the scientific party sent out to explore the Amu Darya, or Oxus, was attacked by about 100 mounted Turcomans, who were, however, repulsed. The whole course of the Amu Darya, as well as of its affluents, is described as having been found navigable.

M. REVAEL, who spent a long time with the Somalis on the western coast of the Gulf of Aden, has described to the Geographical Society of Paris the land and its inhabitants, who appear to be very anxious to trade with Europeans, and he presented an Arab firman signed by the Sultan inviting foreigners to visit his dominions. M. Revael is to return to Somali land with Prince Albert of Monaco.

IN the belief that not much is generally known in England on the subject, Mr. Consul Gollan devotes a considerable part of his last official report to a description of the geographical position, climate, population, industries, &c., of the two provinces of Santa Catharina and San Pedro do Rio Grande do Sul, in Southern Brazil. The former lies between 26° and 29° 30′ S. lat., and 48° 30′ and 52° W. long.; it contains an area of about 14,700 square miles, with a population of almost 160,000. The latter province, usually known as Rio Grande do Sul, lies between 25° 30′ and 32° 30′ S. lat., and 49° 40′ and 58° 20′ W. long.; it has an area of 118,758 miles, with a population of 430,000. The climate, more especially of the latter province, is described as excellent, a term which does not apply to the upper portions of the empire. Being some 700 miles outside of the tropics, these provinces have the advantage of a temperate climate, and are consequently the best adapted to immigration.

A LLOYD'S telegram dated Kobe, October 17, reports the *Vega*, Swedish exploring steamer, arrived at that port on the 14th inst.

SERIOUS preparations for the construction of a railway into the interior of Africa are now being made in France.

French engineers are investigating the territory from the starting-point of the future line to the Laghouat in the south. From that point as far as the line from Ain Sala au Khat military-technical expeditions are to prepare the way. Besides this the Oran Geographical Society and the Vice-Prefect of Tlemcen are to send caravans along the frontier of Marocco. MM. Soleillet and Duveyrier will travel on their own account for the same object.

A MEETING took place at Dortmund on the 4th inst., which had for its object the discussion of a project for connecting the Rhine and the Weser by means of a canal. The Government presidents of Westphalia, of the Rhineland, and of Hanover were present. The canal will be constructed *viâ* Ruhrort and Heinrichenburg, but it is undecided as yet whether from the latter place it will proceed to Emden or to Minden. Special committees were formed for the purpose of further investigating the latter question.

MESSRS. SCHMIDT AND GÜNTHER, of Leipzig, will shortly publish an elaborate work on India by Emil Schlagintweit. The work will appear in thirty-five parts, and will be profusely illustrated by eminent artists.

A PARLIAMENTARY caravan comprising about twenty members of the French Senate and Chamber of Deputies is travelling all over Algeria in order that the legislators may become acquainted with the peculiarities of the land and inhabitants. The tour will be terminated at the end of the month.

THE PLANETS OF THE SEASON

SELDOM could the aspect of the nocturnal sky be more attractive to the student of planetary phenomena; seldom has his inquiring gaze been repelled more pertinaciously by

"Vapours and clouds and storms,"

than during the past anomalous season; and our English climate has more than maintained its accustomed forbidding character, just when a few nights of transparency would have been especially welcome. Better things, however, may still be in store; and in that hope the following remarks on the distinctive features of the present ornaments of our midnight sky may be admissible as possibly of some suggestive value to comparatively inexperienced observers.

We have for some time past had a simultaneous presentation, under the favourable circumstances of proximity to the earth and a greatly improved altitude as compared with recent oppositions, of three peculiarly remarkable objects, the most magnificent, the most ornate, and—so to speak, the most earth-like member of the planetary family. Each holds his own pre-eminence on his own ground; each bespeaks especial study from his own individual character; and it is probable that some acquaintance with foregone results may economise time and labour by enabling us to leave on one side what is already, in comparison, sufficiently known.

The examination of Jupiter is not at present quite as satisfactory as it would be with as much north as he has south declination; it is always, however, greatly facilitated by the broad expanse of his noble disk, and a brilliancy so great as to have occasioned a suspicion of unborrowed light, emanating from internal incandescence. While, however, the shadows of the satellites upon his surface are so intensely black, and the satellites themselves so utterly invisible in eclipse, it is evident that any accession of luminosity from such a cause, even if it exists, must be quite insensible in the general effect, which can only be ascribed to an extraordinary reflective power in the whiter portions of the globe. A diminution of brightness towards the limb, which might be anticipated on optical grounds, and is frequently demonstrated by the reversal of the aspect of a passing satellite from light to dark, or the contrary, is nevertheless not distinguishable by the eye, nor even when a portion of the light has been intercepted by darkening glasses; it is, however, apparent if the screen is deep enough in tint to extinguish the satellites. This was scarcely to be expected. It might have been supposed that a central region so bright as to exhibit a white disk in front of it as dark, even to blackness, by contrast, could not escape being itself strongly contrasted with a border so much fainter that the same disk appears luminous on it as a background. Yet the difference is not obvious; and no other cause can be assigned excepting the imperceptible gradation. The idea of absorption in the upper region of an extensive atmosphere, not otherwise manifesting its existence, has indeed been entertained; but it seems unnecessary. The observed decrease of brilliancy is only what would result from obliquity of incidence in the solar rays, and it probably exists in no greater proportion than is due to that cause. The atmospheric hypothesis might indeed have been directly tested, by comparing the brightness of the satellites when near the limb in the superior and inferior portions of their orbits, had their light been sufficiently equable; but its variations are too evident and at the same time too irregular to render such comparisons satisfactory. A long course of observation might indeed eliminate these discrepancies, but it is questionable whether the result would repay the labour. Nevertheless the fact referred to, of the incompetence of, at least, ordinary vision to detect the diminution of light towards the limb is worth attention, as leading to inferences rather unfavourable to the sensitiveness of the eye in some of the processes of photometry. At a considerable distance from opposition, when the terminator encroaches slightly on the elliptical form of the limb, the defalcation of light on that side may be readily detected.

As to the real nature of that magnificent globe we are compelled to admit an embarrassing amount of ignorance. We see indeed that it is encompassed by an envelope, subject to occasional disturbances of a nature which on our earth would necessarily infer the extensive prevalence of vapour, sometimes in tranquil suspension, at others either agitated by rapid currents, or subject to equally speedy processes of precipitation and solution. Beyond this we can hardly be said to know anything. Jupiter is in no respect an enlarged resemblance of the earth. With so little similarity in point of density and gravitation—with so slight a diversity of seasons—with such rapid interchange of day and night—could we be transported there, we might probably find ourselves as among the imagery of an incomprehensible dream. Vapour we might recognise—and vapour occasionally in a state of rapid change; but possibly not the vapour of water; and whether exhibiting itself in the luminous or shady spaces could hardly be decided by a mere comparison with terrestrial clouds. These would no doubt be to a distant eye brighter than the surface beneath them, but among so much that is dissimilar a single point of analogy would hardly bear much weight; it is, however, the more probable alternative that the dark bands are the transparent part of the atmospheric envelope, from the fact that these become less distinct towards the limbs. The obliteration is not indeed always apparent, and is often absolutely imperceptible in a sharply defining instrument; but it has been frequently referred to, and if these ideas are correct, it may probably be found that in proportion to the darkness of the belts will be the nearness of their approach to the edge of the disk. The disappearance of dark spots near the limb would be accounted for by the rules of foreshortening in perspective.

The tendency to an equatorial arrangement in these streaks is one of the most familiar features of the planet; and almost self-evidently connects itself with the astonish-

ing velocity of rotation; yet there is a "missing link" which cannot readily be supplied. Friction against a surrounding medium, *combing out*, as it has been expressed, the vapours in a longitudinal direction, can hardly be admitted on mechanical grounds; and there is difficulty in conceiving the arrangement of the restoration of equilibrium in currents which set in one direction over the whole visible globe, if they originate by ascending from warmer depths, and lagging behind in a higher and more swiftly rotating region. We may remark, in passing, that only a trifling elevation of the luminous above the grey region, with a corresponding slight difference in velocity of rotation, is compatible with the undeviating contour of the limb as far as our telescopes may show it; though, of course, given an unlimited duration of time, the slightest preponderance would be ultimately adequate to such an effect. Possibly the best explanation may lie in some modification of electrical or magnetic polarity. At any rate the influence, though predominant, is not irresistible, since it neither precludes the formation of belts of a certain amount of obliquity, nor mixes up in confusion, though it seems to elongate, those very remarkable insulated luminous masses which occasionally encompass the gigantic equator in a comparatively equable series with a string of great oval beads, sometimes so curiously and uniformly shaded as to convey an almost irresistible impression of high relief. This strange phenomenon, not confined, as Dawes has found, solely to the equator, seems wholly beyond our conjectures. Nor can we satisfactorily explain those large spots, much darker than the belts, as though the atmosphere were there more perfectly transparent, which have occasionally shown such remarkable persistency as to indicate some relation to definite regions on the surface beneath them; at other times have disappeared with startling rapidity; and usually have been so far from absolute immobility that every attempt to determine the rotation by their means has ended in mere approximation. The occasional detection, too, of many minute white specks, like passing satellites, in various parts of the disk, has added nothing to our knowledge beyond the fact of their presence. The abnormal flattenings of the limb which have sometimes been noticed on the approach of a satellite, or even without it, seem to be of an illusory nature. And yet nothing should pass without attention.

Few things in this wonderful planet are more striking than the singular and beautiful colouring which occasionally adorns the disk. For a considerable season nothing beyond some feeble tinge may be made out, especially in the equatorial zone; then again we shall find purple, brown, greenish yellow, orange, and rosy tints marking out the surface with delicate but unmistakable variety. The darker the grey of the belts, the more apt it is to show a slaty purple hue; the polar regions sometimes, as at present, differ slightly in tint, so that temperature does not seem to be connected with it. The rosy spot of the present season south of the equatorial zone has naturally attracted much attention, and will of course be carefully watched. But as yet the origin of such varieties of colour sets conjecture at defiance. To depict these many changes both of form and hue will always be an interesting occupation, though it is never likely to have any more definite result than to deepen our sense of the wonders of creation, and our reverence for its First Great Cause.

One caution may be permitted here. It would be very desirable for those who attempt to delineate this magnificent planet that they should make themselves familiar with the perspective of a globe. The telescopic image has so precisely the aspect of a flat disk that it requires some mental effort to realise the fact that we are gazing on a great ball; and unless this is carefully borne in mind our drawings will and must be unsatisfactory. Especially it is perhaps seldom imagined how very little we know of the Polar regions, from an obliqueness of presentation amounting to virtual and unbroken concealment. From the analogy of Saturn we may infer that the poles of Jupiter present no remarkable feature; but it must ever remain a mere conjecture to all future generations.

It scarcely needs to be mentioned that no circular representation of the disk can ever give a resemblance tolerable to an experienced eye. An elliptical outline, apparent even with a power of 30 or 40, is too striking a characteristic not to affect materially the faithfulness of the picture.

Something remains to be said as to the beautiful retinue which attends on this leader of the planetary system and whose perpetual change of configuration is ever a source of fresh interest. In some respects they are subjects only for the finest telescopes, in others a very slight optical power can deal with them. The true dimensions of those minute disks are, perhaps, as fairly known as can be expected from measures of such difficulty; but the subject of their numerous changes of brilliancy, though frequently treated, cannot be said to be fairly exhausted. That such changes exist, and to an extent easily recognised in very moderate telescopes, is undeniable; and were they constant for the same orbital positions, they would find ready explanation in the very natural supposition that they rotate like our own satellite, each on his own axis, in the same time that they complete their monthly period. But this idea, though it approved itself to Herschel I. and Schröter, is found inconsistent with observation, which shows the changes to be too irregular in their returns; and we can only infer, what, indeed, has been actually shown by good instruments, both in front of and outside of the face of the primary, the variable darkening of portions of their disks, a result which, interpret it how we may, by atmospheric change, or unsymmetric rotation, or a combination of both (and no other supposition seems to occur), removes those little bodies still further from our analogies. There is no more resemblance between these satellites and our moon than there is between the primaries on which they respectively attend.

We must postpone our remarks on Saturn and Mars to a future opportunity.

T. W. WEBB

NORDENSKJÖLD'S ARCTIC VOYAGES[1]

IT is fifteen months, our readers will remember, since Prof. Nordenskjöld left Hammerfest in the *Vega* to prove that, if taken at the proper time, the North-East Passage is perfectly practicable. And the result has proved that he was right to within a day or two. Nearly a year ago he had practically accomplished the passage, and was only overtaken by the ice just as he was about to emerge into the Pacific. We know already that during their year's enforced imprisonment in the ice to the east of Serdze Kamen, Prof. Nordenskjöld and his accomplished and well-selected staff have made the best possible use of their time. We have already, on several occasions, briefly referred to some of the valuable results obtained in various departments of science, and the full narrative of the expedition will be looked for with impatience. We hope that it will be given to the world with the least possible delay after the leader's return to his home in Stockholm. Meantime we are concerned, not with this culmination of a long series of expeditions in the Arctic waters to the north of the Old Continent, but with the exploring work of its leader during the previous twenty years. Mr. Leslie has done good service in wading through the voluminous literature of Nordenskjöld's various expeditions, and culling from it the material wherewith to compile a

[1] "The Arctic Voyages of Adolf Erik Nordenskjöld, 1858–1879." With Illustrations and Maps. (London: Macmillan and Co., 1879.)

volume of genuine interest and of much scientific value, well provided with maps, and rendered attractive by numerous illustrations.

Mr. Leslie gives a preliminary account of the life of his hero, mostly in the latter's own words, and this is perhaps the most interesting part of the volume. Many of our readers do not need to be told that Prof. Nordenskjöld is a remarkable man, altogether apart from the long series of explorations in which he has done so much for a scientific knowledge of the Arctic regions. Nordenskjöld is a native of Finland, having been born in 1832, the descendant of an old family of good position. His father was chief of the Mining Department of Finland, and a well-known naturalist. Other members of this family were eminent in various departments of literature and science, and the grandfather, Col. Nordenskjöld, built a peculiar residence at Furgord, where stores of natural history have been collected. Here young Nordenskjöld was brought up, and while yet a boy was an industrious collector of minerals and insects, and was permitted to accompany his father on his tours, acquiring thus early the keen eye of the mineralogist. After attending the Gymnasium of Bergo for some time—

"Nordenskjöld entered the University of Helsingfors in 1849, devoting himself chiefly to the study of chemistry, natural history, mathematics, physics, and above all, of mineralogy and geology. 'Already before I became a student,' he writes, 'I had been allowed to accompany my father in mineralogical excursions, and had acquired from him skill in recognising and collecting minerals and in the use of the blowpipe, which he, being a pupil of Gahn and Berzelius, handled with a masterly skill unknown to most of the chemists of the present day. I now undertook the charge of the rich mineral collection at Frugord, and besides, during the vacations, made excursions to Pitkeranta, Tammela, Pargas, and others of Finland's interesting mineral localities. By practice I thus acquired a keen and certain eye for recognising minerals, which has been of great service to me in the path of life I afterwards followed.'

"After passing his candidate examination in 1853, Nordenskjöld accompanied his father on a mineralogical tour to Ural, devoting most of his attention to Demidoff's iron and copper mines at Tajilsk. Here he planned an extensive journey through Siberia, but the breaking out of the Crimean war put a stop to it.

"'After my return,' says Nordenskjöld, 'I continued to prosecute my chemical and mineralogical studies with zeal, and wrote as my dissertation for the degree of Licentiate a paper "On the Crystalline Forms of Graphite and Chondrodite," which was discussed under the presidency of Prof. Arppe on February 28, 1855. The following summer I was employed on a work of somewhat greater extent—"A Description of the Minerals found in Finland," which was published the same autumn. Various short papers in mineralogy and molecular chemistry were printed in "Acta Societatis scientiarum Fenniæ;" I also published, along with Dr. E. Nylander, "The Mollusca of Finland" (Helsingfors, 1856), as an answer to a prize question proposed by one of the faculty. In the interval I had been appointed Curator of the Mathematico-physical Faculty, and had obtained a post at the Mining Office as mining engineer extraordinary, with inconsiderable pay, and an express understanding that no service would be required from me in return. A salary was also attached to my curatorship.'"

Nordenskjöld did not, however, long enjoy these, his first paid appointments. Finland has never taken kindly to her severance from Sweden and her attachment as a province to Russia. Nordenskjöld naturally had a great love for Sweden, and on one or two occasions gave expression to his feelings in speeches at social gatherings. These expressions were certainly not significant of anything like disloyalty to Russia, but the shortsighted governor of the time magnified them into something like high treason. The result was that Nordenskjöld left Finland in 1857 and took up his residence in Stockholm; since then he has been to all intents and purposes a subject of the Swedish Government, and has risen in his adopted country to high honours. Shortly after his arrival he was appointed assistant to the celebrated mineralogist, Mosander, and in December, 1858, on the death of the latter, succeeded him as Professor and Intendant of the Mineralogical Department at the Riks-Museum of Copenhagen. Before this he had travelled and studied in various parts of Europe, especially in Berlin, had visited the Ural Mountains, and explored part of Finland. Since then he has more thoroughly explored Finland and visited many parts of the Scandinavian Peninsula, as a mineralogist. We need not remind our readers of the great amount of work done by Nordenskjöld, during the past twenty years in mineralogical investigation; his researches in this department have entitled him to take a high rank in his own department.

As a scientific explorer, Nordenskjöld is mainly known in connection with the work he has done in the five expeditions to Spitzbergen, of which he has been a member. These expeditions, it should be remembered, were not undertaken for the mere purpose of creating a sensation by the foolhardy feat of attempting to reach the pole at all hazards. Geographical discovery certainly formed a part of the programme of all the expeditions in which Nordenskjöld has been engaged, and on these occasions it was attempted to push as far north as was consistent with safety. In the expedition of 1868, for example, the *Sofia* succeeded in sailing to 81° 42′ N. in 17° 30′ E. long., 12′ beyond Scoresby's farthest; and in the spring of 1873 an attempt was made in man-drawn sledges (thirty-nine of the forty reindeer had bolted, and were never seen again) to push beyond the Seven Islands, but the condition of the ice was such that Nordenskjöld prudently abstained from risking his men's lives. The vessels in which the various expeditions have sailed have been of very small tonnage, in one case only $26\frac{1}{4}$, but this Nordenskjöld considered an advantage in pushing through the drift-ice. The expenses of the expedition have always been moderate, partly defrayed by Government, but mostly by private subscription; as our readers know, one of the most liberal supporters of Nordenskjöld's exploring undertakings has been Mr. Oscar Dickson, the wealthy Gothenburg merchant, to whom Mr. Leslie's volume is appropriately dedicated. The results obtained in these modest and inexpensive expeditions contrast strongly with those of the expensive and elaborately equipped expedition in the *Alert* and *Discovery*. On all these expeditions Nordenskjöld has been accompanied by a competent scientific staff, and the results obtained, both in the natural history and the physics of the Arctic region, have been of the first importance. By means of these and other researches the Riks-Museum of Stockholm has now, probably, the richest collection in mineralogy in the world.

On the first two expeditions to Spitzbergen, in which Nordenskjöld was engaged, 1858 and 1861, he acted as geologist under the leader Otto Torrell, the head of the Swedish Geological Survey. On the former of these several parts of the west coast were visited and explored. At Bell Sound, on the south-west of the main island "dredging was undertaken with abundant success, birds and mammalia were shot and prepared, a tertiary formation containing fossil plants discovered, and botanical collections made, particularly of mosses and lichens. "On July 6 they left this anchorage to sail northwards, but calms and head-winds compelled them to seek the north harbour in the same fjord. There Nordenskjöld discovered thick vertical strata of limestone and siliceous slates rich in fossils of the genera Productus and Spirifer, and which therefore appeared to belong to the carboni-

ferous formation, and found these strata overlain by other nearly horizontal beds belonging to the same tertiary formations with impressions of leaves as he had observed at Middle Hook."

The expedition of 1861 consisted of two tiny vessels. They managed to sail right round the west and north coast to the entrance of Hinlopen Strait, which divides the main island from North-east Land, anchoring in Treurenberg Bay, the starting-point of Parry's famous sledge expedition of 1827.

"The Swedes paid a visit to Hecla Cove, Parry's harbour, protected from the north by Cape Crozier with its hill of quartzite. It was on this point that Parry and his lieutenant, Crozier, carried on their magnetic and astronomical observations, and on this height they erected a flagstaff with a copper plate bearing an inscription to preserve the memory of their visit. Here was found a flagstaff, which, however, was only the highest portion of Parry's flagstaff, and the copper plate was cut away so that only a few small pieces remained under the heads of the nails with which it had been fastened. Hecla Mount, about 1,720 feet high, was ascended, and from its top an extensive view was obtained of North-east Land, which along the coast is very flat with rounded hills of inconsiderable height, and in the interior is covered with a continuous snow-plain of about the same or somewhat greater height above the sea than the top of Hecla Mount, and to the south of Niew Vriesland, the interior of which is also occupied by a similar unbroken snow-plateau. In the neighbourhood large masses of hyperite were found; and to the iron which the eruptive rock contains the Swedes attributed certain irregularities which appeared in the magnetic observations. Interesting as was the discovery of this rock on the other side of the bay to the geologists, it was not so to the physicists, who found that all their magnetic observations were affected by its presence."

Cape Chelyuskin, the Northernmost Point of the Old World.

During the weeks that elapsed from the imprisonment of the vessels in Treurenberg Bay till their release, the zoologists carried on dredgings, the other members of the expedition were employed in copying charts, with a view to future excursions, and in calculating observations; on board the *Æolus* meteorological observations were taken hourly; measurements were also made of the tides.

"At length the ice broke up, and on July 2 the ships got out to sea accompanied by the *Jaen Mayen*, a fishing vessel that had been imprisoned along with them.

"June is the spring month of Spitzbergen. The sun rose higher and higher above the horizon, and his rays were by no means powerless. The snow first became soft and water-drenched, and disappeared in spots from the ground. On June 11 *Cochlearia fenestrata*, and the polar willows began to open their buds; on June 22 the first expanded flowers of *Saxifraga oppositifolia* were gathered, a sign that the midsummer sun had at length won a victory over the northern winter, and on the 26th there were in flower *Draba alpina*, *Cochlearia*, *Cardamine bellidifolia*, and *Saxifraga cernua*, and here and there *Oxyria*, and the willow, and in the beginning of July *Cerastium alpinum*. Small *Poduri* hopped about in a lively way among the snow. By June 7 there were seen on Hecla Mount, more than 1,500 feet above the sea, a number of gnats, and on the 21st there were captured near Æolus's cross *Diptera*, which, however, were unable to raise their wings to a higher flight than a foot or two from the ground. Small spiders and a kind of worm, like our dew-worm, living in the already thawed ground, were found here and there."

After the ice broke up Torell and Nordenskjöld undertook a boat journey down Hinlopen Strait, during which a variety of important data were obtained and collections made. At several places they found immense glaciers,

one about seven miles long, and standing out into the sea with its perpendicular walls. South of Wahlenberg's Bay a bed of Permian fossils in great abundance was met with; these were the first fossils found in North Spitzbergen. After collecting a large quantity of fossils at Angelin's Mount, on the south-west of North-East Land, the party rowed along the shore to another mountain, 2,000 feet high, which strongly resembled it. This they named Lovén's Mount. Its upper part consists of hyperite, and with its flat, steep, and black sides strongly resembles a roof. Underlying the hyperite are horizontal lime- and sand-stone strata with nearly perpendicular faces towards the sound giving the whole mountain the appearance of a regular colossal building. Another rich collection of fossils was made here. The party then proceeded down the strait, but after two hours' rowing were met by fast ice which obliged them to turn. They then rowed along the west side of the sound, taking an hour to pass a broad glacier. After it they came to another which lay like a stratum of rock on a perpendicular cliff of hyperite, and accordingly tumbled with its ice over the rocks into the sea. The hyperite was found to be beautifully polished and marked, and here, as at several other places, were found many signs that the ice in former times had occupied a larger area on Spitzbergen. Between Dym Point and Cape Fanshawe the Swedes passed the greatest auk-fell they had hitherto seen. Here also was found, rising from the sea to a height of 1,000 feet, a perpendicular wall of hyperite, everywhere split vertically into basalt-like, upright, four- or eight-sided columns, standing free or only connected with the main rock by a small corner, and sometimes crowned capital-wise by a stratum of greyish-white limestone. After passing Cape Fanshawe the party next entered Lomme Bay, on the west side of which they found the largest glacier they had yet seen on Spitzbergen. It is about ten miles wide, and projects into the sound with a curved front. The stratification of the ice is horizontal. At Shoal Point, at the entrance to Hinlopen Strait, the beach was everywhere covered with an enormous mass of drift-wood among which are found pieces of pumice-stone, birch-bark, cork, poles, and floats from the Lofodden fisheries, with other things which had been carried hither by currents from the south. The drift-wood formed a broad line along the beach. Farther up was another line, where the water now scarcely comes even during spring tides, probably elevated by a raising of the land. In this line the drift-wood was far older and undergoing decomposition. While Torell was examining all this, he found among other things a well-preserved bean of the West Indian plant *Entada gigalobium*. This bean, which is upwards of an inch and a half across, floats with the Gulf Stream through the Atlantic, is found not unfrequently on the coast of Norway, and being also found on North Spitzbergen, affords the most convincing evidence that the Gulf Stream reaches this high latitude.

Bean of *Entada gigalobium* (natural size).

After the return from Hinlopen Strait, Torell and Nordenskjöld explored a part of the north coast of North East Land. Near Waygatz Islands, on the south of

In the Interior of King's Bay.

Hinlopen Strait, where one of the vessels lay for some time, the divergence between the marine fauna of East and West Spitzbergen was very striking. Here were found animals belonging exclusively to the fauna of Greenland, seen exceedingly seldom or never on the west coast. As an example of the flora to be found in Spitzbergen and of the thoroughness with which the expedition did its work, we quote the following passage from Mr. Leslie's volume:—

"After various excursions had been made the *Magdalena* sailed from the Norways on the 25th, and after passing Kobbe Bay and South Gat, the sound between Danes' Island and the mainland, anchored in Magdalena Bay. Here, at a height of 2,300 feet above the sea, the following plants were found growing, *Cochlearia fenestrata*, *Cerastium alpinum*, *Luzula hyperborea*, and several saxifrages; lower down, small soft tufts of the Arctic willow, *Alsine biflora*, and several grasses. Out of the gravel there rose nearly a foot high here and there the uncommon *Saxifraga hieracifolia* and *Pedicularis hirsuta* with its reddish head, alternating with yellow *Ranunculi* and bright red patches of the graceful *Silene acaulis*, of which, however, a flower here and there had begun to pale under the powerful rays of the sun, which had already caused several *Drabæ* and the here uncommon *Arabis alpina* to go to seed. High up on the fell grew the beautiful *Erigeron uniflorus*. By the side of the small streams that flowed from the top to the bottom of the mountain were mosses, *Saxifraga rivularis*, *Stellaria eduardsi*, and two species of *Poa*. It is remarkable that the vegetation diminishes quite inconsiderably with the height above the sea, so that almost all the plants that grow near the beach thrive as well at a height of 2,000 feet. The continual sunlight and the insignificant difference in temperature are undoubtedly the causes of this.

"The large granite blocks and broken stones, of which is formed the peculiar beach by which the fells are here almost always separated from the sea, are quite concealed by the most luxuriant moss and lichen vegetation. The grey covering, often six inches thick, is for the most part composed of lichens: *Sphærophoron fragile* and *Cladonia gracilis*, *Stereocaulon paschale*, *Cetraria islandica*—Iceland moss—*Bryopogon jubatum*, *Alectoria thulensis*, *Umbilicaria arctica*, *Solorina crocea* and many others; and among mosses of *Racomitrium lanuginosum*, with stalks nine inches long, *Encalypta rhaptocarpa*, *Gymnomitria* and *Bryæ*, *Polytrichum alpinum* and *Dicranum fuscescens*, &c. While the sloop lay in Magdalena Bay Cape Mitre was visited, a promontory which Scoresby ascended one of the few times he landed on Spitzbergen. When he had reached the summit, he was obliged to sit astride the ridge in order to keep his place. On July 31 the *Magdalena* again put to sea, and the same day anchored in Cross Bay. In this neighbourhood the first known fern on Spitzbergen was found—*Cystopteris fragilis*."

Dredging under the Ice in Winter.

In the neighbourhood of King's Bay, was found a seam of coal, together with impressions of leaves and other parts of plants, showing that there was a period in the development of the globe when spreading forests, composed, it would appear, chiefly of broad-leaved trees, resembling maples, everywhere covered the valleys and mountain-slopes, where now, if they be not entirely filled with thick beds of ice, the Arctic willow, creeping inch high along the ground, is the only representative of plants of the nature of trees.

Thus sailing from one point to another, making boat and land excursions, dredging and collecting plants, animals, fossils, and minerals, and studying ice and other physical conditions, the members of the expedition carried on their work, returning only when the ice threatened to lock them in for the winter. This is a fair example of the methods and results of the various expeditions in which Nordenskjöld has been engaged.

In the third expedition to Spitzbergen, in which Nordenskjöld was engaged, that of 1864, he himself was leader. The vessel was an old but strongly-built gunboat, the *Axel Thordsen*, of 26½ tons, part of the object of the expedition being to complete the preliminary survey to ascertain the possibility of measuring an arc of the meridian. On this occasion the expedition succeeded in landing on Bear Island, but on a subsequent expedition it was explored for five days. On the visit of 1864 Nordenskjöld inserted a water-mark at the Burgomaster Port, to register the rise of the land, which is going on in Spitzbergen as in other Arctic lands. After attempting

Stor Fjord, the expedition made for Ice Fjord, which, at its east end, sends off three branches. A careful examination was made of several parts of the coast of this fjord, and in the neighbourhood of the North Fjord Nordenskjöld collected a large number of triassic fossils, among them large nautilus-like shells and fragments of bones, some of which were thought to have been four feet long, belonging to crocodile-like animals. While in Ice Fjord, the expedition met with Mr. Birkbeck's yacht *Sultana*, "a beautiful but fragile nutshell," having among others on board, Prof. Newton. Here also a water-mark was fixed. After leaving Ice Fjord, the *Axel Thordsen* succeeded in reaching Stans Foreland, a large island to the south-east of the main island, having on its south the Thousand Islands.

"Fortunately it appeared that the discouraging descriptions of the fogs prevailing here are properly applicable to the Thousand Islands, comparatively clear weather, on the contrary, being common in the inner part of the fjord. Here, as at many other places on Spitzbergen, may be found cloudless skies and sunshine, while an impenetrable fog lies at the mouth. The cause of this is to be sought for in the course of the marine currents. While an arm of the Gulf Stream, as the masses of drift-wood heaped up at South Cape and the Thousand Islands show, at least during a portion of the year, flows past the southern part of West Spitzbergen and Stans Foreland, it is the Arctic current entering from Helis Sound and Walter Thymen's Strait, which principally prevails in the interior of Stor Fjord. There is, therefore, no drift-wood to be met with on the shores of this fjord, on which account it is necessary on boat voyages to carry a supply of fuel. During boat voyages along the north coast of Spitzbergen one may, on the contrary, nearly always reckon on finding in the neighbourhood of the resting-place dry and excellent material even for a large log fire."

The west coast of Stor Fjord is occupied by enormous glaciers, which go down to the sea and are only interrupted by black, often conically-shaped mountain tops. On the east coast, on the contrary, between Whales' Point and Helis Sound, there is only a single considerable glacier, the coast being formed of a continuous rocky wall, which rises almost directly from the sea to a snow-free plateau of about 1,000 feet in height. At the foot of this wall there are here and there grassy slopes, which form the finest reindeer grounds on Spitzbergen. The west coast both of Stans Foreland and of Barents Land was examined as far north as the extremity of the fjord. In connection with this part of the expedition's work, some interesting remarks are made on the character of the Spitzbergen glaciers:—

"When icebergs are spoken of in the region of Spitzbergen, it ought to be remembered that what is meant is large blocks of ice which fall down from the perpendicular sea faces of the glaciers. Though these blocks are often exceedingly large, they cannot in any way be compared with the icebergs in the Greenland waters, which are said to reach a height of 1,000 feet. The glaciers on Greenland near the sea are indeed higher than on Spitzbergen, but this dissimilarity is not sufficiently great to explain the great difference in the dimensions of the glaciers at the two places. There is great probability in Prof. Edlund's hypothesis that the larger icebergs are formed by blocks of ice falling down from a glacier coming in contact in their lower parts with an over-cooled stratum of water which, as is well known, in contact with actual ice immediately assumes the solid form. For any such over-cooled stratum of water can, on account of the Gulf Stream, only exceptionally occur on the coasts of Spitzbergen, while the contrary is the case in the waters of Greenland, which are taken up almost exclusively by the Arctic current. The ice seeds which have fallen from the glaciers thus find only at Greenland a suitable soil for their further development, only there do they grow to enormous ice-masses, which are so often the cause of the navigator's astonishment and alarm."

(*To be continued*)

HERING'S THEORY OF THE VISION OF LIGHT AND COLOURS

A FEW years ago Herr Ewald Hering, Professor of Physiology at Prague, communicated to the Imperial Academy of Sciences at Vienna a series of six papers propounding a new explanation of the physiology of vision, so far as concerns the perception of light and colour. The papers were subsequently collected and published in a separate form,[1] and have had a wide circulation. The author is well known by his researches on various physiological subjects, and has long devoted attention specially to the phenomena of vision, many of his views having been discussed at much length in Helmholtz's "Handbook of Physiological Optics," published between 1856 and 1866.

The principles developed in the papers in question have attracted much attention on the Continent, and, it is believed, have been thought well of by many competent authorities. So far as I know, however, no account of them, beyond meagre notices of a few lines, has yet been made accessible to English readers. It is highly desirable, both for the reputation of the author and for the information of those of our countrymen who are interested in the subject, that this want should be supplied, and I propose now to offer to the readers of NATURE an abstract of Prof. Hering's theory, sufficiently explicit to enable its general nature to be understood, but at the same time not so full as to supersede reference to the work itself by those who desire to appreciate the reasoning more thoroughly.

The theory of the perception of light and colours at present best known and most generally adopted, is the one formed on the views of Thomas Young, and further elaborated by Helmholtz in his great optical work—hence called the Young-Helmholtz theory. That which Hering proposes to substitute for it may rather be considered as an extension and an improvement than an opposing theory, inasmuch as its chief aim is, by the introduction of additional elements, to account for phenomena which, according to the previous hypotheses, are left obscure, or receive insufficient explanations. This consideration will insure for the theory a more favourable reception than if its object were completely to overturn received ideas. It is not, however, intended here to offer any discussion of the theory; we have only to state what its general features are.

In the first place, it should be explained that the theory is developed chiefly in regard to the vision of black and white, and their mixture, gray. The subject of colour is introduced afterwards, following out the same principles.

The reasoning is founded for the most part on a class of visual phenomena of a subjective nature, such as the effect of contrasts, appearances after looking steadfastly at objects, and so on. These phenomena have long been considered important in regard to the theory of vision, and they are treated of by Helmholtz at much length. The author, however, contends that the endeavours made to explain them have been hitherto imperfect, inasmuch as it has been necessary to call in for this purpose the aid of psychological considerations, such as the effect of imagination and other causes of deception. As he expresses it, on every other page of a professed treatise on physiological optics, one finds the mental judgment invoked as a *deus ex machinâ* to explain any sort of diffi-

[1] "Zur Lehre vom Lichtsinne." Sechs Mittheilungen an die kaiserl. Akademie der Wissenschaften in Wien. Von Ewald Hering, Professor der Physiologie in Prag. Zweiter Abdruck. Wien, 1878.

culty. He objects to this, alleging that these phenomena ought to be capable of purely physiological explanations, and he considers that, when properly investigated, they afford the best means of determining the true character of light-vision.

Acting on this idea, he devotes his first three papers to an examination of these subjective phenomena. He describes a series of experiments of great simplicity, illustrating the various points of importance, and he founds upon them, as he goes on, a chain of reasoning which leads up eventually to the statement of his doctrine. It will be necessary briefly to notice this introductory matter.

The first paper treats of what the author calls "Successive Light-Induction," which he illustrates in several different ways.

If you look steadfastly for, say, fifteen seconds to a minute, at the centre of a small white circular disk, laid on a large black ground (white paper on dull black velvet is best), then, closing and covering the eyes, you will soon perceive a negative after-image (*Nachbild*) of what you have seen. The disk itself will appear dark, generally much darker than the general visual area, and will be sharply defined, but it will be surrounded by a peculiar "light-space" (*Lichthof*), brightest close to the disk, and becoming gradually darker as it recedes, until it fades into the general dark area around. The appearance is that of a halo, or more exactly that of the sun during a total eclipse, where the intensely black circle is seen surrounded by the corona.

This phenomenon is usually explained as follows:—There is a certain internal light-stimulus which acts when the eyes are closed; but the part of the retina which has been exposed to the bright light from the disk has become fatigued thereby and is less sensitive to the internal light-stimulus than the parts around; so that the fatigued circle appears darker than elsewhere. This explanation, which is purely physiological, answers very well so far as the disk is concerned, but it gives no account of the surrounding light-space, for which the psychical *deus ex machinâ* is called in, it being asserted that the halo is only a mental delusion caused by the contrast between the dark circle and the less dark space around. The author objects altogether to the sufficiency of this suggestion, and has devised an experiment to show that the appearance of the light-space is a real and not an imaginary one.

He proves that when the light-spaces of two neighbouring dark negative after-images are superposed, they cause an increase of brightness. To show this, cut out two squares of white paper and place them side by side on the black ground, leaving a small interval between them. Observe then, as before, fixing the eyes steadfastly on a point in the black interval. In the after-image it will be noticed that the narrow intervening strip is much brighter than the space around the other three sides of each square, showing the effect of the superposition in that place of the two light-spaces together.

For a further study, examine the negative after-image of a narrow strip of black paper laid on a white ground; and direct attention first to the absence of any partial darkening of the general ground close to the strip (which ought to result if it were merely the impression of contrast), and, secondly, to the intensity of the brightness of the image of the strip itself. Lastly, to prove that this brightness is far greater than can be due to the self-working inner light-excitation of the retina, an ingenious experiment is shown (easy to carry out, but somewhat lengthy to describe), by which an objective test of the strength of the illumination can be made. The negative light after-image of a black stripe is found, by direct comparison, to be much brighter than a certain amount of objective light thrown on a fresh and unused part of the field of vision, proving, therefore, that the former must be due to something more than the mere unfatigued inner light of the retina.

In concluding this paper the author gives some general conclusions from these experiments. From an analogy with certain effects of colour, he names the light produced in the after-image, around a dark area, *induced light*, and the general effect *successive light-induction.* This takes place on any part of the retina where there has, in the object originally looked at, been a boundary between light and dark, the light part inducing an impression of light in the neighbouring part, so that when the eyes are shut the latter appears bright. The induced light is naturally most powerful in the immediate neighbourhood of the boundary, and diminishes as the distance from this increases, until it fades into the general aspect of the visual field. The author draws two important conclusions from this part of the investigation: (1) that the activity of one part of the retina corresponds with that of others, the usual idea of the independence of each part being untrue; (2) that the so-called independent or inner light of the retina is capable, within certain physiological limits, of being considerably increased in intensity. The phenomena of light-induction are subsequently examined more fully from a more general point of view; in the meantime it is considered as sufficiently shown that the ordinary fatigue theory is not sufficient to explain the appearances observed.

The second memoir is on "Simultaneous Light-Contrast." The author begins with the simplest example:—If a strip of gray paper is placed alternately against a black and a white background, in the former case it will appear much lighter than in the latter. The psychical theory explains this as a false mental judgment, assuming that the absolute sensation conveyed by the gray paper to the eye is the same in both cases. The author controverts this, insisting that the impression is, as a matter of reality and not of imagination, different in the two cases, which he proves by the following experiment:—Make a ground half white and half black, and lay two narrow strips of the same gray paper parallel to each other and a short distance apart, one on each half of the ground. The one on the white ground will look so much darker than the other, that a new-comer would scarcely believe they were both the same shade. Now fix the eyes for half a minute or a minute intently on a point midway between the strips; then close and darken the eyes and observe the after-image. The difference in luminosity of the two strips will be even greater than the apparent difference of shade in the original. And as this after-image cannot recognise any matter of judgment, but only faithfully records the actual state of the retina, it proves that the difference in shade observed was real, and not imaginary; and the inapplicability of the false-judgment-by-contrast explanation is manifest by the fact that the difference between the two strips will often remain after the background, forming the contrast, has disappeared.

The author then goes on to give his explanation of simultaneous contrast, namely, *that the light-perception of any part of the retina depends not only on the illumination of that part, but also on the illumination of other parts adjoining.* He adds that as in modern physiology it is customary to explain the varying strength of reaction consequent on a uniform stimulus, as varying *excitability* (*Erregbarkeit*), it may be said that here the effect of contrast is due to the fact that the excitability, and consequently the excitement, of one part of the retina is a function of the contemporary illumination of the whole retina, or at least of the parts immediately around.

The next step is to point out the connection that exists between the effect of contrast treated of here, and the light-induction described under the former head. The phenomena of successive light-induction showed that a part

of the retina illuminated either not at all or very faintly, but whose immediate neighbourhood was brightly illuminated, gave, in the negative after-image, a much stronger brightness than one, the neighbourhood of which was not so illuminated. The phenomena of contrast show, on the other hand, that the light-perception of a weakly illuminated part of the retina is diminished when its surrounding part is brightly illuminated. Thus the lowering of the perception of brightness (or excitement) *during* the observation of an object, corresponds to the raising of this perception in the *after-image*, so that the successive light-induction appears as the opposite or reversal (*Gegensatz*) of the simultaneous contrast-action. And the latter may be denoted as a simultaneous negative light-induction.

It is, therefore, easy to imagine an internal causal connection between both phenomena, and to consider the lowering of the light-perception (excitability) which takes place during the contrast, as the cause of the raising of the perception which takes place afterwards.

The third memoir treats of "Simultaneous Light-Induction" and "Successive Contrast." To illustrate the former, look fixedly at any point in a line dividing a black space from a white one; after looking some time you will see that the originally deep black begins to lighten into gray; the brightening is the greatest close to the division line, and diminishes farther away, but after sufficiently long observation it will extend more or less over the whole black field. A contrary effect takes place, but less prominently, in the other half, the white darkening in a similar way.

This appearance is usually explained in the following half physiological, half psychological way. From the increasing fatigue of the retina, the white sensation becomes gradually weaker, and, as a consequence of this, the contrast action between the white and the black becomes weaker, and the latter appears lighter, through the same false judgment invoked to explain contrasts generally.

To show the insufficiency of this explanation the following experiment is proposed. Put a strip of black velvet on a white ground, well lighted by a gas flame; after observing it steadfastly for a time gradually diminish the light, and it will be seen that the black strip becomes brighter, and the white ground darker, until at length the former appears actually *lighter* than the latter. If the explanation is applied to this it must be assumed that the fatigue of the retina has become so great that the moderated white produces actually a less powerful impression than the black stripe, which gives out light of very small intensity, or in other words, that the power of the retina is so crippled that a moderate light is no longer able to produce an impression equal to the inner self-illumination of the unfatigued organ. This can be also shown by another trial which is described.

A further experiment enables a direct comparison to be made. In the middle of a broad white stripe laid on a black ground, cut a longitudinal opening; this will show an internal black stripe, surrounded by a white surface which is again surrounded by a black ground: then fix the eyes on the middle of the figure, and, after observing some time, gradually reduce the light. It will soon be found that the black internal stripe appears *lighter than the external black ground*, although both are objectively equally dark, and the parts of the retina brought into action are, as it is said, equally free from fatigue.

The changes consequent on the reduction of the illumination show that the simultaneous light-induction passes over into the successive, the latter being, indeed, only a more clearly manifested continuation of the former. The connection of the three phenomena hitherto treated of may be illustrated simply as follows:—When you first observe a line of division between dark and light, the dark part, especially near the division, appears darker than it would do if the white were absent; this is *simultaneous contrast*. Continue the fixed observation a longer time, and the darkening gradually changes to a contrary effect of brightening, which also is most powerful near the division; this is *simultaneous light-induction*. Lastly, close and darken the eyes, and this brightened space continues a long time visible in the after-image. This is *successive light-induction*.

The last of the subjective phenomena treated of by the author he calls "Successive Light Contrast." It differs from the three last mentioned in that, while they all refer to the comparison of one visual space with another close adjoining, this refers to a comparison of the impressions derived from the *same* space at two successive times. The simplest example is as follows:—Put a strip of white paper on a black ground, and observe it steadfastly for a time; then let it be suddenly removed, keeping the eyes fixed on the same spot. A negative after-image will result, of a changeable character, but showing generally a space corresponding to the paper, much darker than the already dark ground. This is very striking; an inexperienced observer will be loth to believe that he can see anything darker than the blackest velvet; but there can be no mistake about the impression conveyed. The usual explanation of this is that the part of the retina stimulated by the white paper is more fatigued than the rest, and therefore, after it is removed, is less sensitive to the faint light given off by the black ground, making it thus appear still fainter. The author deems this explanation insufficient, as it is inconsistent with many of the changing phases observed in the after-image; and he describes several other experiments to support this view. He points out that the "successive light-induction," before described, may play an important part in these phenomena, but he does not attempt here to give any complete explanation of them.

It is pointed out at the close of this part of the subject that many of the experiments may be made with colours, instead of with simple light and shade, it being understood that black and white hold the same relation to each other, for this purpose, as blue and yellow, or red and green.

WILLIAM POLE

(*To be continued.*)

ALFRED HENRY GARROD

It has seldom been our lot to have to record the premature close of a career so full of promise as that which ended with the death of Alfred Henry Garrod, at his father's house in Harley Street, on Friday last, October 17. The son of an eminent physician, Dr. Alfred Baring Garrod, F.R.S., he was born in London on May 18, 1846, received a medical education at King's College, London, and in 1868 entered St. John's College, Cambridge. He graduated (B.A.) in 1871, taking the highest place in the natural science tripos. In due course he took his M.A. degree, and was elected a Fellow of his college in 1873. His earliest scientific predilections were chiefly for mathematics and physics, and the knowledge of these subjects which he acquired when a student was of great value to him in his biological researches. The mechanics of physiology was the subject to which he first turned his attention as a scientific investigator, and, while still an undergraduate, he communicated a paper on the cause of the diastole of the ventricles of the heart to the *Journal of Anatomy* (vol. iii., 1869). About the same time he sent to the Royal Society the results of an interesting series of experiments made upon himself with a view of ascertaining the causes of the minor fluctuations in the temperature of the human body while at rest, from which he concluded that these fluctuations mainly result from alterations in the amount of blood exposed at the surface to the influence of absorbing and conducting

media. These were published in the *Proceedings* of the Royal Society, vol. xvii., 1869. A series of papers in the *Proceedings* of the Royal Society and in the *Journal of Anatomy* followed, giving the result of observations upon the circulation of the blood, conducted with great ingenuity by means of the sphygmograph, aided by various modifications and improvements upon the original instrument due to his inventive and mechanical skill. It is, indeed, probable that physiology is the subject to which he would most willingly have devoted his attention had not his energies been turned to the pursuit of morphology by his receiving the appointment, in January, 1872, of Prosector to the Zoological Society. This appointment is one which, perhaps more than any now existing, comes near to an ideal endowment of research. An unlimited amount of new material is placed in the hands of its occupant there are no duties beyond those of making and recording original observations, and ample facilities are given for the publication and illustration of all the observations made. To the efficient performance of the duties of this office Mr. Garrod applied himself with great energy and zeal, as testified by his numerous contributions upon the comparative anatomy of the vertebrate animals, which have enriched the publications of the Society, from the date of his appointment to the present time. He devoted great attention to the anatomy of birds, hitherto too much neglected, and his observations upon their myology and visceral anatomy were beginning to throw some light upon the very difficult and obscure subject of the mutual affinities of the members of this class. The curious and most unexpected variations in structure often revealed in the dissection of species thought to be closely allied, soon convinced him of the necessity of far more extended and minute observations than had previously been made, and those who closely watched his work and knew that besides the observations he had had time to complete and publish, he had already accumulated a vast mass of facts, partly in notes and drawings and partly in the stores of his memory, feel most keenly how much has been lost by his early death.

His eagerness in acquiring knowledge was only equalled by his activity in imparting it to others, and he had a remarkably easy and lucid method of explaining, even to an uninstructed audience, difficult problems of physiology or anatomy. With the black-board or some ingeniously contrived diagram or mechanical illustration, he was never at a loss to make his hearers comprehend his meaning. These great and varied powers probably tempted him to overtask his strength. Not content with his work at the Zoological Society, he sought for and obtained the Professorship of Zoology and Comparative Anatomy at King's College, in 1874, and the Fullerian Professorship of Physiology at the Royal Institution in 1876. He was also appointed one of the Examiners in the Natural Science Tripos at Cambridge in 1875, and was for several years a constant contributor to this journal. In 1876, when he had but just completed his thirtieth year, he was elected a Fellow of the Royal Society.

In the simple and single-hearted devotion to the sciences he cultivated, he was without a particle of jealousy or mistrust of others, but was always anxious to assist those who were working in the same direction, and his room at the Zoological Gardens was gradually becoming the profitable resort of many of the younger workers at comparative anatomy, who were encouraged in their labours by his advice and example.

Up to little more than a year ago he was apparently in the enjoyment of vigorous health, but symptoms of the insidious disease, phthisis, which terminated his existence, then for the first time showed themselves. Through the gradual decline of his powers, and amid considerable suffering, borne with the greatest patience and calmness, he continued to the last to spend all his remaining strength in making the knowledge which he had acquired available for the instruction of those that should come after him.

W. H. F.

JOHN MIERS, F.R.S.

THIS well-known botanist, whose death took place on the 17th inst., was born in London on August 25, 1789, of Yorkshire parents. After leaving school he devoted his time to the study of mineralogy and chemistry, in which latter science he made a series of important researches, but it was only subsequently during his long residence in South America that he acquired his taste for botanical knowledge, and by making dissections and drawings of plants he became a botanist. In 1825 he paid a short visit to England and then published his "Travels in Chili and La Plata." In Brazil, where he subsequently resided eight years engaged in his professional engineering labours, he made extensive collections of plants and insects. After his return to England he was elected a Fellow of the Linnean Society in 1839 and a Fellow of the Royal Society in 1843, acting for a time on the Council of both societies. He contributed many papers of interest to the Linnean Society, and published the "Illustrations" and the "Contributions" to South American Botany. He served on the jury of the Brazilian Section of the Exhibitions of 1862, and of 1867 of Paris, and for his labours the Emperor conferred on him the honour of Commander of the Order of the Rose. His zeal and energy in his pursuits were most untiring, and he only desisted from his labours when forced by failing health in July last, since which time he gradually became weaker, till death ended his life on the 17th inst. in the ninety-first year of his age. It is understood that Mr. Miers has left his botanical collections to the British Museum.

As a botanist, Mr. Miers was most painstaking and accurate in his investigation of details. His descriptions, and especially his original drawings, afford ample evidence of this. On the other hand, his estimate of the relative value of the details he elaborated with such zeal and care was often at fault. His observation was keen and accurate, but his judgment was less to be relied on. It is on this account, probably, that multitudes of species and, in lesser numbers, genera, and even orders, proposed by him, have not been generally accepted by his brother naturalists. Mr. Miers, we believe, never adopted evolutionary views, but remained a believer in the fixity of specific types. What, however, is more remarkable is that to the last he disbelieved in the action of the pollen and of the pollen tube in the formation of the embryo plant. In this particular Mr. Miers probably stood alone among his fellows.

But whatever difference of opinion may exist as to the value of his inferences, there can be none as to the laborious accuracy of his descriptions, the fidelity and beauty of his drawings (too often spoiled in the reproduction), and the generous kindliness of the man.

NOTES

M. RAOUL PICTET has been appointed Professor of Physics by the Council of State of Geneva, at the University of his native city.

M. KRANTZ, the director of the Paris Exhibition of 1878, is publishing the lectures delivered at the Trocadero. It will consist of no less than thirty-five thick 8vo volumes, five of which have already gone through the press.

AT the meeting on October 7 of the Manchester Literary and Philosophical Society, the president, Dr. Joule, described a simple means for checking the oscillations of a telescope. It consisted of a leaden ring placed centrally about the axis of the

tube of the telescope and attached thereto by three or more elastic caoutchouc bands. He had employed two of these rings for his telescope, one placed near the object-glass, the other near the eye-piece. Their united weights were only one-quarter of that of the telescope tube, but nevertheless they diminished the time required for the cessation of vibration to one-sixth of what it was before their application.

IT is curious to see the impression which the electric light has made on two semi-civilised monarchs, the recent barbarities of one of whom at least have proved him to be little better than a savage. The King of Burmah, the papers tell us, has recently ordered a wholesale importation of electric lighting apparatus; and from a note in the last number of *Les Mondes* we learn that the Shah of Persia has had the light introduced into Teheran, showing an intelligent interest in its working under the direction of a Frenchman, M. Fabius Boital. So pleased was his Persian Majesty with the display that, *Les Mondes* states, he "decided on the creation of a palace of industry, the construction of which he has confided to M. Boital." Let us hope that the Shah will continue in this laudable frame of mind, and be led on to introduce many of the other beneficial applications of science into his ill-governed country.

MR. FRANCIS GALTON has reprinted, with some additions, an abstract of his Royal Institution lecture on Generic Images. Appended are some interesting autotype illustrations showing the result of composite likenesses of Alexander the Great and Napoleon I., and the composite result of likenesses of six Roman ladies and of eighteen criminals.

MR. R. IRWIN LYNCH, late of the Royal Gardens, Kew, has been appointed Curator of the Cambridge Botanic Garden, in place of the late Mr. Mudd.

THE following scientific missions have been authorised by the French Government for this year:—Ernst Chartre, of the Lyons Museum, is to carry out anthropological investigations in Kasan, the Caucasus, the Crimea, and Turkey; Emil Rivière, prehistoric researches in the department of Alpes Maritimes; and Paul Sárda to investigate the geology of the soil of Japan, and visit the most important mining districts.

DR. KARL RUSS, the well-known ornithologist, has, in his serial *Isis*, issued a request to all sportsmen in Germany to abstain during the present shooting season from killing hares and partridges, as he opines that in many places both kinds of game would be completely exterminated if his warning is not heeded. Sportsmen in this country would perhaps also do well to give the subject some consideration, as there is no doubt that the two species named must have suffered considerably from the unfavourable weather which prevailed during the last spring and summer.

EARTHQUAKES are reported from Klagenfurt and Grafenstein in Carinthia. At the former place a violent shock was felt on the 1st inst. at 2h. 20m. 25s. A.M. The phenomenon lasted for 2–3 seconds, and was accompanied by loud subterranean rumbling. The direction in which it proceeded was north-north-east to south-south-west. At the latter place a shock was felt on the 1st inst. at 2h. 5m. P.M., also accompanied by a rumbling noise; direction, west to east. In the Chinese provinces of Shen-Si and Kan-Su earthquakes have quite recently caused much damaged. It would seem that the earthquake which occurred on Friday and Saturday, the 10th and 11th inst., extended over a far wider area than had at first been reported. Shocks of greater or less violence were felt not only all over Eastern Hungary, but throughout Transylvania, Servia, Roumania, and even Bessarabia. The phenomenon manifested itself in Belgrade at half-past four in the afternoon of the 10th, and lasted eight seconds, the direction of the motion being north-north-east and south-south-west. In Weisskirchen there were two violent shocks felt on Friday afternoon about a quarter before five o'clock. Further shocks were experienced at half-past seven, and again on Saturday morning at a quarter to five, and all through the night slighter quakings and oscillations of the earth were constantly being repeated. A large number of chimneys were thrown down, and a number of houses were cracked and otherwise damaged at this place. From Temesvar it is reported that a number of shocks, one rapidly succeeding the other, were felt, the ground oscillating under foot. The shocks in Karansebes were so violent as to dash plates and dishes from their shelves to the ground, while to people in the street the ground appeared to rock with an unsteady motion like that of a vessel on a rough sea.

WE have more than once remarked on the extreme incompleteness of the indices to that most valuable journal, the *Quarterly Journal of Microscopical Science*. The index to the new volume (xix.) is not even as complete as the table of contents. It is in the interest of both zoology and botany that we make these remarks.

M. EDOUARD SARASIN has recently established a registering limnimeter, similar to those of MM. F. A. Forel and Th. Plantamour at Geneva, in a locality close to Vevey, near the eastern extremity of the Lake of Geneva. Several observations which he has made since the establishment of the instrument fully confirm the results of the investigations of Forel on the state of permanent oscillation of the fluid mass. The times of maxima and minima of the height of the water coincide with those which are observed at Geneva, showing their predicted alternation, and following an analogous period of seventy-eight minutes.

THE establishment of the electric light at the British Museum appears to have been successful. Eleven lights in all have been fitted up, and of these four are placed in the reading-room, four in other parts of the building, and three outside it. The four in the reading-room are placed, one in the centre and three equidistantly around it. They are supplied with continuous currents, each from its own Siemens dynamo-electric machine. Of the lights in other parts of the Museum, two are placed in the entrance-hall, one in the reading-room corridor, and one in the Greek gallery. In the courtyard in front of the building are two more lights, while another is placed in the rear, near to the engine and machine-house. These seven lights are supplied from one Siemens machine, producing an alternating or divided current. It will thus be seen that two different systems of electric lighting are employed, both, however, being on the Siemens principle—the four lights in the reading-room being produced by continuous currents, and calculated to be each equal to 4,000 candles, the seven other lights, which are estimated at 400 candles each, being produced by an alternating current, and being connected in one circuit about 1,200 yards in length.

THE Indian Museum will be finally closed to the public on Saturday.

THE laying of the new cable from Marseilles to Oran, in Algeria, has been attended with several mischances. The operation has been executed in a singular manner. The *Dacia* laid down the land cable from Algiers and steamed to Marseilles, in order to begin the operation from France. The end of the land cable had been buoyed, but when the *Dacia* tried to pick it up to connect it with the end coming from France, it broke. The *Dacia* and *Charente* tried to recover it with grapnels, but up to the present time without any other result than deteriorating the existing cable, which is now out of use; so that instead of having two cables, the capital of Algeria has none. All the messages were sent by the Bone line, which is encumbered by work, being mostly devoted to messages from

Tunis and Tripoli. We believe the cable has at last been successfully laid.

In the note in NATURE, vol. xx. p. 563, on the elevations attained by railways, mention is omitted, Mr. D. Sharp writes us, of the Spanish lines which are so remarkable in this respect. The northern line is at the sea-level at San Sebastian, but attains a height of 614 metres, between Zumairaga and Alsasua; after descending from this, an elevation of 934 metres is reached, between Briviesca and Burgos; and after a long transit, 1,359·88 metres (4,476 feet) is touched by the railway while traversing the Guadairama about thirty miles from Madrid. The line from Santander to Alar del Rey reaches an elevation of 984 metres in passing the Cantabrican chain near Reinosa, and in the distance of 33 kilometres between Barcena and Reinosa, mounts 560 metres. The southern line from Madrid to Cordova does not reach such great elevations as the North Spanish lines; nevertheless, in passing the Sierra Moreno, it attains the considerable altitude of 798 metres, or 2,630 English feet above the sea-level.

It is stated that the heavy rains in Assam have flooded part s of the country and threaten serious damage to tea prospects. Some of the gardens are reported to be looking very unhealthy and yellow.

Her Majesty's Consul at Panama reports that india-rubber has almost ceased to be an article of export from the isthmus, mainly in consequence of the great difficulty and expense of getting at the trees in the remote districts of the interior. Those nearer the coast have been destroyed by the wasteful system pursued by the natives in cutting down the trees to procure the sap.

The German Society for Cultivation and Acclimatisation of Birds will hold its fifth exhibition at Berlin on November 21–25 next. Cage-birds in the widest sense of the word, and park-birds generally will form the principal objects of the exhibition, which will also include stuffed specimens, skeletons, skins, nests, and eggs, as well as all apparatus and paraphernalia applying to the object of the Society. Those of our readers interested in ornithology who wish for further particulars should apply to Herr H. Schmidt, 32, Lothringer-Strasse, Berlin, N.

At Pritschaberg, near Nassenfus in Lower Carniola more than 4,000 Roman copper coins have recently been found. Most of them were contained in an earthen jar and many others surrounded this; the whole was imbedded in the ground close to a road and at a depth of only half a metre. The coins are tolerably well preserved and date from the reign of the Emperors Severus (A.D. 193 to 211), Gallienus (254 to 268), Claudius (268 to 270), Aurelianus (270 to 275), Tacitus (275 to 276), and Probus (276 to 282). The greatest number date from the reigns of Aurelianus and Probus. The jar and coins were evidently buried during the reign of the latter, as not one coin dating from the reign of his successor Diocletian is amongst the number.

In a recent paper to the Berlin Academy, on Progress in Knowledge of the Chemical Nature of Meteorites, Prof. Rammelsberg states that since he wrote in 1870 a paper on the Chemical Nature of Meteorites, more than twenty meteoric irons and about as many chondrites have been obtained and examined, besides some meteorites belonging to the more rare species; and he therefore thinks it desirable to make a fresh survey of the subject. He adopts Prof. Rose's classification. Among other points noticed are the discussions relating to the iron masses of Ovifak. The presence of nickel can no longer be regarded as a sure sign of the meteoric nature of iron masses. The small group of pallasites has been increased by one new member, the bronzite-pallasite of Rittersgrün (found in 1833 and recognised as a meteorite since 1861, but its true nature only determined lately by Weisbach and Cl. Winkler). Specially interesting is the occurrence of a white mineral (asmanite) consisting entirely of silicic acid, found in the Rittersgrün meteorite, as also in that of Breitenbach. A second representative of the rare meteorites which are free from metallic iron has been found in the Ibbenbühren stone (which contains Fe.3Mg). The first was the stone of Manegaum, purely bronzite. Recent researches on meteoric iron do not elucidate certain chemical differences of physically distinguishable parts, to which the earlier works of Reichenbach and Meunier referred; nor is the nature of the crystalline combination schreibersite more exactly known. (For further details we must refer to the *Monatsbericht*.)

Through a recent landslip at the Salzberg, Hallstadt, a wooden structure was laid bare, in excavation of which were found a number of bones and tools, which appear to have belonged to the period of Celtic interments at the Salzberg. Among these objects was an implement (of unrecognisable nature) with a thick blue coating, which, on examination by Herr von Hochstetter, was found to be covellin or protosulphide of copper, the interior being copper. The coat was 0·5 to 1 ctm. thick, and showed a composition of 32·81 per cent. sulphur, and 64·45 per cent. copper. Its specific gravity was 4·611. The copper below presented a much-corroded surface, and in the hollows were spherules of arragonite about 2 mm. in diameter. The conditions of eating away of the copper and complete transformation of it into protosulphide of copper were furnished (says the author) in the burial-ground containing gypsum and greatly permeated with decaying animal and vegetable remains. From the gypsum and organic remains there would be formed abundant sulphide of calcium, which would cause transformation of the copper according to the formula—

$$Cu + SCa + CO_2 + O = SCn + CO_3Ca,$$

or $$Cu + SCa + (CO_2)_2 CaO + O = SCu + 2CO_3Ca.$$

We receive from America details of the accident which terminated for this year the career of the New York captive balloon on August 16, the very day when the Paris captive balloon was torn to pieces by the wind because it had not gas enough to sustain its spherical form. The New York balloon was sent up with two persons only as a trial, and rose to 800 feet when it burst. The two passengers were precipitated to the ground, but no harm was done to them, the balloon having acted the part of a parachute. The bursting was inevitable, the balloon having been started full of gas and the neck having been fastened with a rope. The rent extended from the top to the equator.

The *Times* Paris correspondent states that at Guisseny, Finistère, a cave 15 metres long by 4 wide has been discovered under a heap of rocks. One entrance faces the sea at a height of 4 metres, and the other the land, so that it must have been well adapted for watch and defence. Below a layer of ashes were found stones laid together, human bones, remains of funeral urns, evidently Celtic, a considerable quantity of animal bones, some of them apparently of extinct species, and a stone hammer and polished porphyry hatchet.

We have received a pamphlet of fifteen pages entitled "Notes on the Flora of Hampshire," by F. Townsend, M.A., F.L.S. This consists principally of two carefully drawn-up lists or tables of plants. The first list comprises plants found on the Hants mainland but absent in the Isle of Wight or in one or more of the adjacent counties of Wilts, Dorset, Sussex, Surrey, or Berks. The second list is that of plants absent on the mainland in Hants but found in one or more of the counties referred to above. By the first of these lists Mr. Townsend points out "that of the seven floras enumerated those of Surrey and of Sussex more nearly

approach that of Hants, the former possessing 176, the latter 174 of the 242 species found in Hants mainland but absent in one or more of the adjacent floras; the maritime or coast plants being deducted, in order to compare a county not possessing a coast with one possessing such." Regarding the second list the author says:—"We should naturally suppose . . . the floras of Surrey and Sussex would again be shown to approach the flora of Hants mainland by thus possessing fewer species not found in the latter, and that the floras of Wilts, Berks, and Wight (which by the first list are shown to be most dissimilar from Hants mainland, for Wilts possesses 121, Berks 109, and Wight only 96 of the 242 species in List No. 1) would possess many more species not found on Hants mainland than would Surrey or Sussex; but the reverse is the truth, for these two last named counties are shown by List 2 to possess more species not found on Hants mainland than Wilts, Berks, Wight, or Dorset possess." The author advances an explanation for this apparent contradiction and concludes his "Notes" with "a few words on River Basin Districts," explaining why he "would choose them for showing the geographical distribution of plants in preference to civil or artificial divisions." The value of such notes as these is by no means slight; those before us, we are told by the author, have been published principally in the hope that they may be seen by competent botanists who may have it in their power to communicate additional species or perchance point out errors so that their insertion may be prevented in the flora of Hampshire, which Mr. Townsend hopes soon to publish.

The additions to the Zoological Society's Gardens during the past week include two Rhesus Monkeys (*Macacus erythræus*) from India, presented respectively by Dr. Douglas and Mr. R. C. Bonsfield; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. T. Hobbs; a Bonnet Monkey (*Macacus radiatus*) from India, presented by Mrs. Bonamy Dobree; two Arabian Gazelles (*Gazella arabica*) from Arabia, presented by Capt. W. Bowden Smith, R.N.; a Great Bustard (*Otis tarda*) from Spain, presented by Mr. George G. Sandeman; two Chinese Tree Pies (*Dendrocitta sinensis*) from China, presented by Mr. Chas. Rice; a Common Waxbill (*Estrelda cinerea*) from West Africa, presented by Mr. J. C. Thorowgood; a Sun Bittern (*Eurypyga helias*) from South America, deposited; a Bosman's Potto (*Perodicticus potto*) from Sulymah, South-West Coast of Africa, two Crested Colins (*Eupyschortyx cristatus*) from Mexico, purchased.

THE SANITARY CONGRESS

THE Sanitary Science Congress opened its proceedings at Croydon on Tuesday under the presidency of Dr. B. W. Richardson, F.R.S., who spoke of the success which had attended the work of the Institute. In the evening a general meeting was held in the great public hall to hear the address of the president. As a sort of complement to his previous address in an ideal city, under the title of Hygeia, Dr. Richardson this year, under the title of Salutland, sketched an ideal land, polity, and people. He introduced his fancy sketch as follows:

"On the 19th of July of this year, at the home of the Father of modern Sanitary Progress, who has this moment resigned the chair to me, I met the most illustrious of now living men of science. Our conversation turned on many subjects, all of which were lighted up by the entrancing exposition which always gilds the genius of him to whom I specially refer, Prof. Owen. One subject peculiarly attracted the attention of us who listened to him as he expounded it. We had entered into a discussion on the question of the longevity and the natural duration of life of different classes of animals. With his usual scientific accuracy and industrious research, Owen had on that day estimated, from various data he had collected, the natural term of life of the curious animal, the hippopotamus. He had learned that its term of life was thirty years. He explained to us the mode by which he had arrived at that fact: how into the calculation it had been necesssary to take into account the dentition of the animal; the stages of development; the natural wearing out of the teeth; the period of gestation; the development of the skeleton into the perfection of a bony fabric, with particular reference to the combination of the epiphyses or loose ends of the bones to the shafts of the bones; and, lastly, the pathological or diseased condition of the dead animal of the species that had arrived at its full longevity, in order to determine whether or not there was evidence of cause of death from disease of some particular organ, or whether there was no such evidence, but simply a history of general decay from old age pure and simple.

"We were told that in a hippopotamus which had recently died, and which was known to have just turned thirty years of age, the two sets of teeth had fulfilled their allotted duty; that the bones of the skeleton were duly consolidated; and, that the organs of the body were equally degenerated; so that death had occurred, not from failure of any particular organ, but from failure of the organic parts altogether. In a sentence, the animal had died a natural death, and the constant of the term of life of it and its family was set down at thirty years, a constant to which all the facts that could be collated in respect to this species of animal definitely pointed.

"From this line of facts in respect to one type of animal life we were led to others, and the rule, laid down by the distinguished Flourens, by which the determination of natural old age is calculated on the basis of perfected maturity, was brought under review. The skeleton is perfected when the epiphyses or loose terminal parts of long bones are firmly united with the shaft of the bone. When the date of such perfection of development is known in the mammalian class of animals, the simple process of multiplying the age at that date by five, gives the natural anatomical life of the animal. The elephant came before us as an example. A young elephant, whose history has been related in the *Philosophical Transactions*, died at the age of thirty years. At that age the epiphyses of its bones were not completely united with the shafts. It was nearly but not quite matured. Multiply thirty by five, and one hundred and fifty years stand as the natural estimate of the life of the elephant, so that really an elephant might exist which had itself carried all the Governors-General of our Indian Empire. Moving from this animal of long life, we turned to the camel, to find full maturity at eight years, full life at forty. We turned to the horse, to find full maturity at five years, full life at twenty-five. We turned to the lion and the ox, to find full maturity at four years, full life at twenty. We turned to the dog to find, full maturity at two years of age, full life at ten. We turned to the cat, to find full maturity at eighteen months, full life at seven and a half years. We turned to the rabbit, to find full maturity at one year, full life at five.

"From these contemplations our minds very naturally reverted to the animal, man, to the members of the human family. Man, we learned, follows the same rule as the rest of living beings. Judged by the same test, his full maturity and full age may be calculated with equal precision. His maturity, —perhaps not quite the full maturity,—is twenty years. His full age, therefore, is one hundred years. This is the anatomical estimate of human life, the surest and by far the best of all that can be supplied, since it defines a law irrespective of and overriding all those accidental circumstances of social and physical storm and strife, which may interfere, and indeed do interfere, with every estimate based on the career of life itself, as it is shown in the ephemera by and through whom it is phenomenally demonstrated.

"This lesson, told with singular felicity of language from two masters of science,—for Owen never forgot Flourens,—struck Mr. Chadwick and myself with singular force. On a surer basis than we ever trod, it corroborated a view we had ourselves promulgated from entirely different stand-points; and it further corroborated a similar view which had been advanced by our eminent friend, Dr. William Farr. We were led, in a word, once again, to the inevitable conclusion that man, even in this stage of his probation on the planet, is naturally destined to walk upon it, endowed with sensibilities of life and intelligence, for a period of one hundred years, and that until he realises this destiny practically, he is in value of physical life actually degraded far below his earth-mates, whom he designates the brute creation, and over whom he presumes to exercise his, to

them, almighty will. The constant of human life is naturally one hundred years.

"In this statement I, for one, gathered up, on the occasion referred to, something never to be forgotten. The constant was before us in all its truthfulness. But more remains. Because the fulness of age is one hundred years, it is not an essential that death shall immediately crown the advent of that fulness. To certain parts of the scheme of natural life there is a boundary. The period of maturity of development has its boundary of twenty years; when the body, as Flourens says, ceases to grow; but if it ceases, in the ordinary sense of the term, to grow it does not cease to increase; its nutrition improves and perfects for twenty years more at least, and then only has reached its completed physical condition. It should never from that period gain in weight, and for a long time it should not lose. It goes on now through a third period, which Flourens admirably calls the period of invigoration, during which all its parts become firmer, all its functions more certain, all its organization more perfect; and this period covers thirty years. At seventy old age begins; the *first* old age, in which naturally the fruits of wisdom are most bountifully developed, and which lasts from fifteen years to twenty, to mellow down to a period of *ripe* old age, commencing at eighty-five years and lasting fifteen years more, *i.e.*, until the constant is attained.

"And yet there need not now be death; for though, as Lord Bacon has said, old men are like ruined towers, and though, as Flourens has quoted, youths live in a double sense, with forces in reserve and forces in action, *vires in posse et vires in actu*, the *radical* forces and *acting* forces of Barthez, while old men live only on the forces in action, '*vires in actu*,' possessing no reserve, it is wonderful how the forces in action will continue after the reserve is withdrawn. This kind of half-life has continued unquestionably many years beyond the fulness of age, both in man and lower animals, and to give it twenty years beyond the natural hundred is to be just without being in any extreme sense generous.

"In this anatomical reading of human life we see the growth, the increase, the invigoration, and the solidification, of the body: we see the life with its reserve on its two threads; the life without reserve on its one thread; and, finally,—the force in action being withdrawn—the life ceasing, and the earth, proclaiming her mastery, dragging the actor as unconsciously to herself at death, as he was unconsciously projected into the world at birth.

"All through this presentation of natural fact, moreover, there runs another physical truth. Death is centripetal action. Those two birds on the wing which up to heaven's gate sing, are physically filled, like the gyroscope, with the *vires in posse et vires in actu*, powers in reserve and powers in action. Yon wanton sportsman liberates a ball which pierces one bird, and the earth claims its prey. The living gyroscope falls. The fellow bird escapes. In time, it fails to rise to the same height, its force in reserve being withdrawn, but its force in action remains, and it lives on. At last, some trifling extra call upon it is final, and the triumphing earth brings it down to itself. That first bird fell from an interference with its life while yet it had its two powers; that second bird fell from failure of powers at different periods, but from the same inevitable, always present cause, the attraction of the earth.

"The same is true of men also. What we call death is gravitation: what we call disease, is some accidental shot inflicted, it may be, while still the self-resistance to gravitation is in operation: what we call natural death is the gradual overweighting, at different periods, of the natural powers, reserve and acting, by the persistent force that bears us down. We cease to grow at a certain stage of our life, because of the resistance of this downward force: we cease to increase in size from the same cause: we consolidate in structure from the same cause: we bend in old age from the same cause: and we die from the same cause. Every step has practically been a death from the same cause.

"As these facts appear, we are inclined to ask, How many of all men and women projected into life and charged with the reserve and acting forces,—how many die with these forces intact up to the time of death, and how many with the acting force alone in operation? How many, if I may use the simile, die on the wing, fall headlong to the earth, shot by some wanton shaft that need never have been discharged? How many sink naturally to the earth from her final and gentle embrace?

"The answer to this question appals the mind. The answer rings out:—Man reckless of life! every lower animal you do not immolate beats you in this! Man! civilized as you are proud to say, you have never yet given life a chance! Man of reserve and action, you die on the wing more certainly than the birds of the air on which you practise your fatal sports! You die within the first part of the second third of your natural lives. Let the elephant die at sixty, the camel at sixteen, the horse at ten, the dog at four, the cat at three years, and the rabbit at two years, and they will then match you in the value of life you train yourself to possess. Man, endowed with knowledge of science, who can divide the year into seasons, and history into centuries and eras; who can calculate the courses of the planets and predict their crossings and shadows; weigh the earth, as in a balance, and predicate storms and tempests, you have yet to learn that, with the precision that regulates all these things, your own life is meted out,—that such a childhood means such an adolescence, such an adolescence such a maturity, such a maturity such a decline, and such a decline such a periodof death.

Nay more; man so endowed does sometimes see by adventure, as it were, the whole law fulfilled without his studying for it or expecting it. Some individual lives the whole natural period of life, exceptionally, as an elephant, a horse, a lion, a dog, a cat lives it ordinarily, and thus by adventure, proves the truth of the law which has been laid down. The event, perfectly commonplace in the case of a lower animal,—a dog that lives to ten,—is a perfect marvel when it happens to a man who lives to a hundred years, the equal term. To see a centenarian we travel miles and miles, and discuss the time of his birth with keenest criticism, so truly unnatural is the state of things under which human existence at present is unfulfilled.

"The question arises, How long is this condition of affairs to last? No more vital question stands for solution at the bar of civilisation.

"The day, in fact, has now arrived, when the cultivation of life by the cultivated of mankind is the primary art for the continuance of the cultivated. If the civilised world would continue in the ascendant, it must learn to live. An average life of forty-one and under favourable circumstances of forty-nine years, with a world of disease and death up to that period, and a scattered struggle of the fittest for an exceptional existence into ripe old age, cannot maintain the relative efficiency of any nation, except in a world universally and equally bad. Ingenuity itself is bounded by life; device by faculty for devising. Weapons of precision give us victory over savages. Is that success? Weapons are made, not begotten, and savage tribes, fierce for contest and unscrupulous, may readily learn to apply what the civilised man has devised, and in repetition of history, make easy work of the short-lived civilised.

"We Sanitarians are forced by our studies to recognise these truths. We exist, if we exist for any great purpose at all, to protest against the casting away of nearly two-thirds of the life that is meted out for civilised men. We exist to protest that it is not a scientific civilisation which can permit such reckless waste of the gift that stands above all values and qualities; and our protest is the more earnest as we detect that the waste which we observe, is actually not at the time of life after the prime has been reached, but is most destructive in the very budding of life, and continues at the intermediate stages between the period of budding and the prime.

"To speak in plain terms,—and if ever plain terms were demanded, they are demanded now,—the world in this matter of life and death has, by daily observation of the phenomena, got into the habit of looking on wrong as right, and on what is practically suicidal death as death that is natural. It is a strange fatuity. If we were, for a short time, to see the lower domestic creatures under the same curse; if we were to witness horses enjoying ten, dogs four, and cats three years, as an average duration of their lives, we should think a persistent murrain had come upon them, and that, in relation to these useful domestic animals, the whole course of life had undergone a deteriorative change. Yet that is what, in effect, we are observing amongst our own kind, so that the Sanitarian in despair may exclaim: 'Oh that man were as wise as the horses and dogs, that he might have the bounty of life which the Allwise has awarded to him as the natural bounty, extended and beautified and exalted by the intelligence with which he is endowed above the beasts.'

"I press the question. Why should we, of all animals, perish as we do in the first part of the second third of our

natural career? Why are all the doctors of the human species, with their flowing knowledge and consummate skill, to carry out cure? Why are they so set at naught, that the lower animals, who have no advantage of their services, have a higher vital possession than man at their command?

"The answer is told in a few words. It is that we have never as a community let ourselves study the question; have never, in truth, looked at the facts, plainly as they stand forth.

"And now comes another question—Knowing the facts; knowing what is the natural term of human life, can mankind learn to attain that term? Can man learn to live his hundred years, with a prospective chance of extension to a fifth of a century more? Instead of being cut down at the moment when he has filled his intelligent mind with the learning of his time, and when his knowledge is just becoming transmutable into wisdom, can he go on, an intellectual being, brought to the highest pitch of usefulness? Can he go on to the full term of his natural and prospective course?

"I do not dare answer that question on my own account, because it is answered for me. He who gave the life has answered the question. He has written it for us in unmistakable language. He has shown all of us who can read His natural designs, that it is one of them that man may live the term if he will. Free-will making a man a free agent, is all that is set above the natural law, and free-will is natural law too, government by intelligence which is as natural, and is as freely supplied.

"How, then, shall civilised man live, that the natural term may be found?"

Dr. Richardson then proceeded to sketch his ideal Salutland, located somewhere to the extreme south of Mr. Hepworth Dixon's "New America," the time being the middle of the twenty-first century. He depicted its polity, its social and domestic life, its people, its work, its sanitary arrangements.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

THE ninth session of the Newcastle College of Science was opened on the 13th inst., when very satisfactory reports of the progress of the institute were made. Prof. Lebour delivered the inaugural address on Some Aspects of Geology. Interesting and genial speeches were given by Lord Ravenworth, the Dean of Durham, and others.

FROM the Calendar of Anderson's College, Glasgow, we see that a very complete education can be obtained at that institution in science and medicine, the fees being unusually low. The Calendar has an interesting sketch of the life of John Anderson, F.R.S., the founder of the college, as also of the institution itself.

M. FERRY, the Minister for Public Instruction, having arrived in Paris, has visited the Observatory and the School of Medicine, where important works are being carried out. One of the peculiarities of the new buildings will be the large number of dissection rooms. More than a hundred tables will be prepared for dissections, so that every student in medicine will be enabled to take part in *épreuves pratiques*, which will be an essential part of the education of medical students.

THE new college so liberally endowed by Mr. Mark Firth, at Sheffield, was opened on Monday by Prince Leopold. The endowment, it is expected, will soon reach 25,000*l.*, and the institution is mainly intended for carrying out the University extension scheme, which has been remarkably successful in Sheffield. The building seems to be altogether satisfactory, and, we are glad to see, contains provisions for experimental instruction in chemistry and physics. Prince Leopold insisted on the great benefits which must accrue to the working classes from the establishment of such an institution.

PROF. MAX MÜLLER, on Monday night, delivered the president's inaugural address on the opening of the winter session of the Birmingham and Midland Institute. His German and Italian friends, he said, while recognising that full political liberty reigned here, thought there was little intellectual freedom, and that, however it might be in London and a few other large cities, the Universities—the nurseries of thought and learning—were fettered by the mediæval spirit of monastic institutions and the principles of scholastic philosophy, which contrasted ill with the freshness and freedom of Continental Universities.

SCIENTIFIC SERIALS

The Quarterly Journal of Microscopical Science, October.—W. B. Scott and H. F. Osborne, On some points in the early development of the common newt, with pl. 20 and 21.—E. Ray Lankester, On the structure of *Haliphysema Tumanowiczii*, with pl. 22, generally confirming the facts recorded by Mr. Saville Kent, and failing to observe the collar-bearing flagellate cells described by Haeckel. Prof. Lankester shows the structure to be however not quite so simple as that which is supposed to characterise the body substance of such Foraminifers as the Lituolida.—E. Ray Lankester, On a new genus and species of Gymnomyxa (*Lethamœba discus*) pl. 23.—H. Gibbes, On the structure of the vertebrate spermatozoon, pl. 24.—Index to volume xix., N.S.

The American Naturalist, September.—Brazilian corals and coral reefs, by R. Rathbun.—The formation of Cape Cod (concluded), by W. Upham.—The hillocks or mound-formations of San Diego, California, by Dr. G. W. Barnes.—Insect powder, by W. Saunders.—Recent literature; General notes; Scientific news; Proceedings of Scientific Societies; Selected articles.

Journal de Physique, September.—M. Bouty here describes some mechanical phenomena which accompany electrolysis; his paper treats (1) of pressures exerted by galvanic deposits, (2) of the action of heat on metallised thermometers, and (3) of peculiarities of nickel.—M. Sebert gives an account of the accelerograph of M. Marcel Deprez, in its most recent form; the apparatus is for measuring pressures developed by gases from powder (which are caused to act on a piston).—There are also notices of M. Deprez's magneto-electric machine (in which a Siemens armature is arranged to work between the branches of a horse-shoe magnet, being about equal to these in length), and a new form of electroscope, by M. Guerout.

Asiatic Society of Bengal, vol. 47, No. 223, N.S., April 6.—Description of *Thaumantis louisa*, pl. 12, from Upper Tenasserim, by J. Wood Mason.—On a great snow-fall in Kashmir, by R. Lydekker.—Physiographical notes, &c., on Tanjore, by Lieut.-Colonel B. R. Branfell.—On the proper relative sectional areas for copper and iron lighting rods, by R. S. Brough.—Description of a new Homopteron (*Cosmoscarta masoni*), by W. L. Distant.—On the Indian species of the genus Erinaceus, by Prof. Dr. Anderson, with 4 plates.—On a supposed new hedgehog (*Erinaceus niger*) from Muscat Arabia, with a plate.—On *Arvicola indica*, Gray, and its relations to the sub-genus Nesokia, with a description of the species of Nesokia (pl. 13 and 14), by Prof. Dr. Anderson; Index to Volume.

Morphologisches Jahrbuch, Bd. 5, Heft 2.—A. Pansch, Memoir on the morphology of the cerebral hemispheres, in mammalia, pl. 14 and 15.—H. Strasser, On the development of the limb cartilages in Salamanders and Tritons, pl. 16-19.—G. v. Koch, Notes on the skeleton of corals, pl. 20.—M. Fürbringer, On the question of the formation of nerve plexi, pl. 21, 22.—C. Semper, Reply to Prof. Fürbringer's article "On Homology." —Prof. Fürbringer, On the chief points alluded to in Prof. Semper's reply.—Notices.

Zeitschrift für wissenschaftliche Zoologie, Bd. 32, Heft 4, August.—On the worm fauna of Madeira, by Prof. Langerhans, pl. 31-33. Describes a large number of new genera and species.—Researches into the structure and development of the Sponges, seventh notice: The family of the Spongidæ, by Prof. F. E. Schulze, pl. 34, 38.—*Typhloscolex mülleri*, W. Busch, being a supplement to notes on the pelagic annelids of the coasts of the Canary Islands, by Prof. R. Gree^c, pl. 39.—On the oral skeleton of Asterids and Ophiurids, by Dr. H. Ludwig.

SOCIETIES AND ACADEMIES

LONDON

Entomological Society.—October 1.—Sir John Lubbock, Bart., F.R.S., president, in the chair.—The President alluded to the loss which the Society had sustained by the death of Mr. Wm. Wilson Saunders, F.R.S., and a former President of the Entomological Society, and announced that the council had accepted the responsibility of awarding two prizes offered by Lord Walsingham and other gentlemen for the best and most complete life-his-

tories of *Sclerostoma syngamus*, Dies., and *Strongylus pergracilis*, Cob., supposed to produce the so-called "gapes" in poultry and other birds, and also the grouse disease. Messrs. Stainton and McLachlan, both objected to the Society dealing with subjects relating to the *Entozoa* which could in no case be considered as entomology, for the study of which the Society was founded, and considered that the matter would have been more properly placed in the hands of the Linnean or Zoological Societies.—Mr. Philip Hy. Gosse, F.R.S., of Torquay, was elected an Ordinary Member. —Mr. McLachlan exhibited specimens of the hemipterous insect, *Anthocoris nemorum*, reported to be doing great damage to hops growing in the neighbourhood of Canterbury, but the exhibitor suggested that it was on the hops in search of aphides or other small insects, and therefore beneficial to the hop-grower. He also exhibited examples of the larvæ of one of the *Embidæ* found by Mr. Wood Mason at Jubbulpore. Mr. McLachlan further called attention to the sculptured stones on the shores of Lake Leman, previously referred to and considered by Prof. Forel to be due to the action of trichopterous larvæ. From a recent examination of many similar stones on the shores of Lake Neuchâtel Mr. McLachlan inclined to the opinion that the markings were caused by Mollusca.—Mr. Pascoe exhibited a specimen of a species of the *Acridiidæ* remarkable for its aquatic habits, which was found in some numbers on the surface of a pool near Pará.—The Rev. A. E. Eaton exhibited larvæ, pupæ, and cases of species of *Hydroptila* (restricted) collected in the neighbourhood of the Haute Savoie, describing their habits and referring to a case of synonymy to which they had given rise.—Sir John Lubbock exhibited a specimen of *Orchesella rufescens* taken in Kent, being a species of Collembola new to Britain.—Mr. E. Boscher exhibited a coloured drawing showing the extreme forms of two varieties of the caterpillar of *Smerinthus ocellatus*, and remarked on their food-plants and habits.—The following papers were either read or communicated :—"Descriptions of Phytophagous Coleoptera," by Mr. J. S. Baly; "Descriptions of New Sphingidæ," by Mr. A. G. Butler; and "On the Affinity of the Genus *Polyctenes*, West, with Description of a New Species," by Mr. C. Waterhouse.

Royal Microscopical Society, October 8.—Dr. Beale, F.R.S., president, in the chair.—Prof. Martin Duncan and four other gentlemen were elected Fellows, and eleven nominations were made for the November meeting.—Several valuable donations to the Society were announced, consisting of a revolving table, a ruling machine, and a clock, and of books, apparatus, and slides, for which special votes of thanks were given to the donors.—Mr. J. Beck read a paper on the structure of the scale of a species of *Mormo*, Mr. Gilburt on the morphology of vegetable tissues, and Dr. Stolterforth on a new species of the genus *Eucampia*.—In the discussion on the papers the President, Mr. Stewart, Mr. Beck, Mr. Gilburt, Dr. Edmunds, and Mr. Crisp took part.

PARIS

Academy of Sciences, October 15.—M. Daubrée in the chair.—The following papers were read :—On the present state and the future of thermo-chemistry, by M. Berthelot. The author presented his new work, "Essai de Mécanique chimique fondée sur la Thermochimie," comprising the matter of some 300 memoirs published in the *Annales de Chimie*, &c. The first of the two volumes treats of calorimetry: its first part expounding the theoretical rules, its second experimental methods, while its third contains numerical data accumulated during the last sixty years by physicists and chemists, on heats of combination and of physical changes and on specific heats. The first part of the second volume comprises the general study of chemical combination and decomposition, and principally that of systems in equilibrium between two contrary tendencies. The next part deals with the fundamental object of the work, the prevision of reciprocal actions of substances, and the rules by which it is determined, which are deduced from the principle of maximum work. This simple principle separates effects due to chemical energies, between particles of ponderable matter, and foreign energies between ponderable matter and the etheric medium. This separation is (in the author's opinion) the chief original feature of the work. The prevision of phenomena, from numerical data of thermo-chemistry seems to him destined to work great changes in chemical science.—Regular alignments of joints or diaclases, in the tertiary strata of the environs of Fontainebleau; their relation with certain features of relief of the ground, by M. Daubrée.—M. Marey announced, by letter, that he had received an electrical Gymnotus alive from Para. Having recovered from the fatigues of the voyage, it now gives strong discharges when touched; it also grows tame and eats gudgeons offered it. It is placed in an aquarium at 25° C. The discharges are not so violent as those of a gymnotus received last year, which, wounded and ill, died soon after being experimented with, and which was probably frightened and angry when touched.—The President announced, with regret, the death of M. De Tessan, Member of the Section of Geography and Navigation.—Production of a new manure capable of meeting the requirements of agriculture, by M. De Molon. He utilises wrack or seaweed, mixing them, in successive layers, in pits, with pulverised phosphate of lime, in proportions suitable for fermentation. The mixture is allowed to ferment six weeks to two months, according to the season, and if the decomposition of organic matter is not completed then, the compost is mixed anew for further fermentation. The manure thus produced contains, besides phosphate of lime, rendered very assimilable, the fertilising elements, nitrogen, mineral salts, potash, soda, and magnesia.—A note by General Ibañez, accompanying the second volume of "Memoirs of the Geographical and Statistical Institute of Spain," was presented. —On the separation of roots of an algebraic equation with numerical coefficients, by M. Laguerre.—Experiments on the electric discharge of the chloride of silver battery, by Messrs. Warren de la Rue and Müller.—Action of metallic nitrates on monohydrated nitric acid, by M. Ditte. Certain nitrates combine with the acid named to form acid salts. Others (of which nitrate of magnesia is a type) are fused, under heat, in their water of crystallisation, which is then liberated along with nitric acid, and there remains a matter containing still more or less water, neutral nitrate, and either a sub-nitrate or an oxide. On contact with the monohydrated acids, the sub-salts are changed into neutral nitrates, setting at liberty some water, which is added to what the matter still contains, and which cannot be separated without decomposing the matter entirely. (The nitrates of manganese, zinc, alumina, iron, copper, and manium, also belong to this group). A third, and the largest group of nitrates, are simply insoluble or extremely little soluble in the acid considered. Nitrate of lead may be taken as a type.—On nitrate of silicium, by M. Schutzenberger.—On the physiological action of *Strychneæ* of South America, by M. Jobert. He has tried several of these, and finds they all act similarly; they are not tetanising, like the strychneæ of Asia. They quickly affect the motor-nervous system, not affecting the sensibility and the circulation. —On the treatment of sympathetic ophthalmia, by section of the ciliary nerves and the optic nerve, in place of removal of the eye, by M. Boucheron.—On the innervation and circulation of the breast, by M. Laffont. The breast contains true dilator nerves, as well as those which, when excited, cause increase in the quantity of milk secreted.—Origin and morphological value of the different pieces of the labium in Orthoptera, by M. Chatin.

STERRY HUNT'S CHEMICAL AND GEOLOGICAL ESSAYS

Chemical and Geological Essays. By Thomas Sterry Hunt, LL.D., F.R.S., &c. Second Edition, revised, with Additions, pp. 489. (London: Trübner and Co., 1879.)

THIS book contains twenty essays, and a preface, itself an essay, some of which were written as early as 1853, and the others have appeared from time to time, either as original contributions, reviews, or lectures. These literary and scientific efforts are but a small part of Dr. Sterry Hunt's contributions to chemical and dynamical geology, but it would appear, from the preface to the first edition, that a selection was made upon a definite idea. The selected essays, as a whole, cover, he considers, nearly all the more important points in chemical geology; and the introduction of one relating to the hypothesis of a cooling globe and of "certain views" of geological dynamics, he considers make together a complete scheme of chemical and physical geology. He was disposed to re-write some of the essays, but this was not done, because they seem to the author to have a certain historic value and serve to fix the dates of the origin and development of views, some of which, after meeting for a time with neglect, or with active opposition, are now beginning to find favour in the eyes of the scientific world. Dr. Sterry Hunt states that his views, for which his fellow-workers were not prepared, were subsequently propounded by them as new discoveries or original conclusions. Five of the papers, moreover, contain, according to the author—writing in 1874—the germs of a philosophy of chemistry and mineralogy which he hopes one day to develop himself or to see developed by others.

There is no doubt that, although Dr. Sterry Hunt may be satisfied that his views are correct on all the very numerous subjects he has entertained, there is not a single chapter, one might say a single page in many, which will not meet with very decided opposition on the part of scientific men who are not likely, in after years, to let their hypothetical conversion precede their assumption of originality.

It is difficult in reading this book, full of good facts, but crammed with hypotheses and arguments about priority of thought, to believe that the author is a most genial man, and who is imbued with the true spirit of science. Very much of the type of the late David Forbes, he really is the last man whom one would believe would be so dreadfully polemical. Yet he must know that the book can only be appreciated by advanced geologists and chemists who really do care that the discoverer of a *fact* or of a *method* should have a proper priority, but who do not care about who first put forward certain *views* on subjects incapable of proof or indulged in scientific *guesses* before the fact. There is no doubt that with regard to a science like that of geology, men working in different countries at the same subject, arrive simultaneously at the truth or what seems to be true in relation to facts which are common property. A register of opinion, whether expressed at lectures, debates, addresses, or published in journals, is clearly impossible. Moreover, there is a great amount of unwritten geology which is common knowledge, but no one thinks it worth while to write it and claim a priority. Hence any one taking up a variety of subjects must suffer from not having his ideas recognised at once and may really be unfairly placed in the background. But as there is usually no intention of an evil character, it is unwise to be so very touchy upon priority in hypothesis. Very characteristic of certain zealous minds, is this everlasting harping on who made the discovery of a fleeting hypothesis first.

On looking over these essays we are struck that whilst a controversy with Dana is recorded, the celebrated reply of David Forbes to some of the author's views is not given. And some of the contributions seem to represent former views of the author, and not those which he has since developed. Mallet will feel uncomfortable when he reads how he has been forestalled in his kinetic theory, but it is satisfactory to have the cap put on the right head. Dr. Sterry Hunt has settled volcanicity, and may be thus quoted: "With the contributions of Vose and Mallet, the theory of volcanic action advocated by Keferstein, Herschel, and myself, would seem to be well-nigh complete." This self-commendation will, however, not establish the nonsense of Keferstein, whom the author terms irrational, or the mere passing expression, without confirmatory facts, of Vose, and it will not enable him to stand on the same footing as the philosophic and modest Mallet.

Should any geologist make an original suggestion, do not advise him to refrain from publication; or if it is to be given to the world, let it be done at once. Otherwise Dr. Sterry Hunt may suffer, as he did in the odd matter of limestones, dolomites, and gypsums, and the illustrious but reticent Cordier. On October 28, 1844, a memoir was deposited with the Academy by this geologist. Being in a sealed packet, writes Dr. Sterry Hunt, its contents remained unknown until after his death, when at the request of his widow the seal was broken. No money was found and not a codicil, but on February 17, 1862, a remarkable theory transcending everything geological and fully explanatory of the formations of those limestones, came to light. It fell flat, for Dr. Sterry Hunt had maintained similar views, or rather more correct views, for four years.

Prof. Ramsay is so hardened a debater that he will not be utterly cast down, it is to be hoped, by having one of his hypotheses snatched from him and placed on the prior brow of our author. It was not for some years that certain *views* of the author on the formation of dolomites "found recognition." "When Prof. A. C. Ramsay, by the investigation of the magnesian limestone of the Permian in England, was led to reject as untenable the notion held by Sorby (and by others) that this was once an ordinary limestone of organic origin subsequently impregnated with magnesian carbonate under conditions not explained; and to conclude that the carbonates of lime and magnesia of which it is composed had been deposited simultaneously by the concentration of solutions due to evaporation in an inland salt lake." To this view as he informs us, he (Ramsay) was led by physical considerations and "by the depauperated condition of the

organic remains contained in these strata, *without being at the time aware that I had twelve years previously announced the same conclusions for all magnesian limestones, and established them on chemical grounds.*" The italics are ours, for Prof. Ramsay's especial benefit. The author concludes his last essay on the theory of types in chemistry, with some good advice to a thoughtless-Sterry-Hunt-neglecting posterity :—" In conclusion I have only to ask that future historians will do justice to the memory of Auguste Laurant, and will, moreover, ascribe to whom is due the credit of having given to the science, a theory which has exercised such an important influence in modern chemical speculation and research; remembering that my own publications on the subject, which cover the whole ground, were some years earlier than those of Williamson, Gerhardt, Würtz, or Holbe." It is a pity that much good scientific work should be encumbered by these vanities, and really much that is objectionable can be compensated by the study of such essays as those on the chemistry of natural waters, which is admirable and suggestive.

THE PHILOSOPHY OF MUSIC

The Philosophy of Music. Royal Institution Lectures. By W. Pole, F.R.S., F.R.S.E., Mus. Doc. Oxon. (London : Trübner and Co., 1879.)

IT has long been felt by intelligent persons anxious to possess some acquaintance with the scientific side of music, that the technical works to which they have recourse for the desired knowledge are unsatisfactory from a logical point of view. We are acquainted with no work on technical music which offers any reasonably intelligent explanation of the basis on which its material is founded; and a school has arisen, no doubt partly as a reaction from the crude speculations and unsupported dogmatism of many standard works, which refuses to acknowledge anything beyond the mere acquirement of technical facility in composition as a desirable object in the study of the so-called science of music.

The work of Dr. Pole appears to be intended as a protest against this limitation. It is an endeavour to make plain so much of æsthetic and physical acoustics, and the *rationale* of technical music, as may enable the musician to give some sort of intelligent reason for the faith that is in him.

Dr. Pole's well-known musical attainments are a guarantee for the soundness of the work so far as musical technicalities are concerned. As to general questions of evolution, the nature and objects of musical grammar, the origin and nature of scales, and of the technical rules of music, we think that this book leads the way among English works, in a logical, or perhaps we had rather say, in a common sense treatment of the subject.

It is useless within the limits of this article to attempt to convey any idea of the arguments employed. For the most part the opinions of Helmholtz have been adopted. Whatever may be the ultimate opinion as to the absolute accuracy of these views, there can be no doubt that their admission changes the fundamental study of music from an unmeaning dogmatism into a science.

The first part of the work gives a sketch of the material of music, and forms a treatise on elementary acoustics. The second part deals with the evolution of melody, the history of the scale, melodic and harmonic relations, rhythm and form. The third part is entitled "The Structure of Music." Its most important items are the history of harmony, and the discussion of its rules, combinations, and progressions. It concludes with a slight notice of counterpoint. The characteristic of the book seems to be that a good idea may be obtained from it of a sound body of musical doctrine, comprising foundation, history, and technique.

We select two or three points for notice, as to all of which we are not perhaps quite in accord with Dr. Pole.

There is something yet to be said as to the difference in the way in which the highly gifted musician and the ordinary listener hear music. The observations on the decay of counterpoint (p. 288) seem to want some notice of this. It is more or less a waste of energy to write music in many parts, all of which are made melodious at some sacrifice of the harmonic effect, when not more than perhaps one in a hundred listeners is capable of hearing more than one melody at a time. We think that it is not the power of writing counterpoint that has died out so much as the will to write it. There can be no doubt that the unpopularity of counterpoint is mainly due to the fact that the ordinary listener is unable to hear in it what the highly gifted musician hears. The many simultaneous melodies are quite lost on the ordinary listener. It is only in the case of the greatest composers, whose principal melodies and harmonies do not suffer by their attention to the counterpoint, that works of this class attain any popularity. Until the acquirement of the power of hearing many simultaneous melodies is placed within the reach of the ordinary listener by a suitable and widespread education specially directed to this purpose, it is useless to look for a popular interest in counterpoint, which shall encourage the composer to produce it. There is a question how far it is possible for a person not naturally gifted with the polyphonic ear to acquire it in perfection. But there can be no doubt that systems of education are possible which will do much towards advance in this direction; and that the direct cultivation of polyphonic hearing and reading is the shortest cut towards the formation of the true musician.

There is an incompleteness in Dr. Pole's statement of Helmholtz's explanation of consonance and dissonance, which is important, as it affects the logical foundation of this part of the work, which however forms but a subsidiary portion of Dr. Pole's book. The point in question has been discussed at large some time ago by Prof. Mayer, Mr. Sedley Taylor, and others. It will be sufficiently explained by quoting the summary of the principles which Dr. Pole employs in the discussion of the examples of chords, and also a passage from Helmholtz which contains the considerations omitted.

(Dr. Pole's book, p. 210.) "Now having given these two data, velocity of beating, and strength of beating notes, we may examine some of the binary harmonic combinations of sounds, and see in what manner and to what extent the partial tones, of which the sounds are made up, give rise to the beating or harshness above described."

The following passage will show that another set of data is required, namely, the law according to which the

production of beats in the ear between pure tones depends on the interval:—

(Ellis's "Helmholtz," p. 260.) "On the other hand we have seen that distinctness of beating and the roughness of the combined sounds do not depend solely on the number of beats. For if we could disregard their magnitudes all the following intervals, which by calculation should have 33 beats, would be equally rough:—

"The semitone	*b' c''*
,, whole tones	*c' d'* and *d' e'*
,, minor third	*e g*
,, major third	*c e*
,, fourth	G *c*
,, fifth...	C G
(to which we may add the octave	C_1 C).

"and yet we find that the deeper intervals are more and more free from roughness."

Helmholtz then proceeds to give an approximate determination of this important law, for which we must refer to his work. Our own impression is that this law is almost solely concerned in the variation of the roughness of different combinations. We ourselves hear the roughness of beats up to very high numbers, and consider that up to high numbers beats of sensible intensity do not fail to be heard by reason of their number only. If this is the case the rapidity of beats must be of less importance in the theory of consonance than the law of dependance on intervals exhibited in the above quotation from Helmholtz.

To show the practical importance of this:—

(Pole, p. 213.) "Here we find the two fundamental notes themselves ($c' - e'$) beating at the rate of 64 per second. . . . This is, therefore, a less perfect combination than the fifth; but still the beats are quick, and the effect is not disagreeable."

This seems to us incorrect. If the 64 fundamental beats per second were present with any intensity to speak of, the combination would certainly be most dissonant. It is because the ear receives the two notes on different parts of the sensorium, and so gets them out of each other's way, that the beats do not exist in sensible intensity, and do not produce dissonance.

In the appendix on Beats, and an essay there referred to, Dr. Pole has developed doctrines which arise to some extent from the point of view above indicated. The statement made is substantially that the beats described by Robert Smith ("Harmonics," 1749), have a real existence, besides the various types of beats described by Helmholtz.

Smith's cycles are best seen if the sum of two harmonic curves be described by Donkins's harmonograph, or some such machine. Smith's doctrine consists of the statement that the cycles which appear in the resulting curves are the cause of the beats. (Of course Smith did not use pendulum-vibrations, but the use of these adapts the doctrine to our modern knowledge.)

Now in order that these cycles may be seen, it is necessary that one and the same scribing point should describe the sum of the two motions simultaneously. If the motion be analysed and its two components be described separately on the paper, the cycles fail to appear.

This is what must happen in the ear if the doctrines of Helmholtz are even approximately true. The two sounds (if beyond the minor third apart) fall more or less completely on different parts of the sensorium, and the conditions requisite in the first instance for the formation of Smith's cycles are not fulfilled. Whether, if the cycles existed, the beats could arise out of them in the way in which we hear them, is quite a different question, on which we will not now enter.

The great importance of this question has induced us to prolong our remarks on it. On these points every student should consult Helmholtz's work. But on the more purely musical questions Dr. Pole's book has its own value.

OUR BOOK SHELF

A Treatise on Chemistry. By H. E. Roscoe, F.R.S., and C. Schorlemmer, F.R.S., Professors of Chemistry in Owens College, Manchester. Volume II. Metals. Part II. (London: Macmillan and Co., 1879.)

THIS portion of Professors Roscoe and Schorlemmer's work treats of the metals of the iron, chromium, tin, antimony, and gold groups, also of spectrum analysis, the natural arrangement of the elementary bodies, and the condensation of the gases formerly called permanent. The treatment of these subjects is characterised by the same accuracy of description and clearness of explanation and arrangement that were so conspicuously displayed in the former parts, and the illustrations of metallurgical operations, &c., are well chosen and admirably executed, such, indeed, as are not to be found in any other English manual of chemistry. Amongst them may be especially noticed the figures of the plant for Weldon's method of regenerating manganese dioxide from chlorine residues, of the various forms of blast-furnace, of the Bessemer and Siemens-Martin processes for making steel, and of hydraulic gold-mining as practised in California. The best methods of detecting and estimating the several metals are carefully described, and interesting details are given relating to their history, some of which will, we think, be new to many readers.

Spectrum analysis, in which Prof. Roscoe is known to be a high authority, is well treated and illustrated, and attention is drawn to recent speculations, founded on spectroscopic observation, respecting the possible resolution of the bodies now regarded as elementary, into still simpler forms of matter. In the chapter on the Natural Arrangement of the Elements, a clear view is given of the remarkable relations between the properties of the elements and their atomic weights, first pointed out by Mr. Newlands, and further developed by Lothar-Meyer, and Mendelejeff; and the volume concludes with an account of the condensation of the gases formerly regarded as permanent, in which the ingenious forms of apparatus employed for the purpose by MM. Cailletet and Pictet are fully described and illustrated.

Altogether the two volumes of the work now published form a treatise on Inorganic Chemistry of which English science may well be proud; and the student who masters their contents will not fail to acquire a sound elementary knowledge of the subject. H. WATTS

Elementary Mechanics, including Hydrostatics and Pneumatics. By O. J. Lodge, D.Sc. Chambers's Elementary Science Manuals. (Edinburgh, 1879.)

THIS is one of the comparatively sound text-books which, since the publication of Thomson and Tait's work, have been every year more effectually thrusting aside the cumbrously artificial and often erroneous introductions to Physical Science which reigned almost unchallenged till about sixteen years ago. Dr. Lodge knows his subject well, and has evidently bestowed very careful thought upon it. Still we cannot unreservedly commend his book; and this for several reasons. First, he evidently proceeds under the idea that the subject can be made

easy to a beginner; that, in fact, there are no real difficulties which must be fairly faced by every student. We are surprised to find that this opinion can be held by any sound and successful teacher. Our own experience has always been dead against it. Dr. Lodge says of the elementary works of Thomson and Tait, Clerk-Maxwell, and Clifford, that they are "far too difficult for beginners." We do not think that his process of dilution makes the matter a whit less difficult. It has rather a tendency to conceal from the reader the place where the real difficulty lies, and a necessary difficulty *avoided* is certainly not *overcome*. Second, the avoidance of difficulties is managed by loose and sometimes even metaphysical language (see, for instance, pp. 83-5); evidently embodying some of the speculations in which the author has indulged while excogitating his work.

As an instance of loose writing take this (p. 16)

"5. The effects of force on matter are:
A. Change of motion, which is called *acceleration*.
B. Change of size or shape, which is called *strain* or deformation.

If only one force acts on a body, it must produce the effect A. If two or more forces act in different directions on a body, they must produce B, and they may produce A also." Now, at first sight, this looks well enough, and certainly Dr. Lodge knows the facts thoroughly. But how is *change of motion* called *acceleration?* Acceleration is correctly defined (p. 19) as *Rate* of change of *velocity*. But (p. 18) velocity is defined as "the rate of motion of a body." Put these extracts along with A above, and we find "change of that whose rate is called velocity is rate of change of velocity;" a very remarkable proposition, indeed one of high metaphysical interest. Again, if only one force act on a body, it *must* produce B unless the body be perfectly rigid. And two or more forces do *not* necessarily produce B, even on the most plastic body. Take the case of two different sets of parallel forces, for instance, each proportional to the mass of the element on which it acts.

In conclusion we may say that for the facts of elementary mechanics, for excellent examples of application of the formulæ, and such like matters, the student may use this work with profit:—but he ought to be warned that where the text appears most simple it is generally loose, often metaphysical, and here and there unintelligible.

Le conchiglie Pompeiane. Descritte dal Dott. Nicola Tiberi. 4to, 12 pp. (Napoli, 1879.)

THIS remarkable and well written memoir was published before the recent celebration at Pompeii of the eighteenth centenary of its destruction by a volcanic eruption of Vesuvius. It is the work of an excellent naturalist, who lives at Resina, close to the site of the ruined city, and who is especially conversant with the shells of the Mediterranean. The point of view to which he directs our attention is very different from that which has been taken by the geologist, antiquary, artist, or architect. He treats of the shells found in the ruins, and which had served for food, or been used by the Pompeians for ornament and other purposes. Indeed we know from Athenæus and other ancient authors that mollusca were then relished quite as much as they are at present by the inhabitants of Italy. I have been unable to discover in the loose and incorrect twaddle of the younger Pliny, who lost his life in the eruption, any mention of shells having been collected by his countrymen for the study of natural history. It is a pursuit or amusement of comparatively modern times. Dr. Tiberi gives a list of all the shells which he has noticed as Pompeian, belonging to no less than 44 species, with particulars of their relative abundance at Pompeii, as well as of their distribution and economy. Some were of eatable kinds, as the common oyster and mussel, *Pecten jacobæus*, *Venus chione*, *Tapes decussatus*, and several species of *Helix*. Others adorned fountains, as *Haliotis tuberculata*, *Murex trunculus*, and *M. brandaris*. The oriental pearl-shell (*Meleagrina margaritifera*) was represented only by a single valve. But the ladies of Pompeii seem to have attached considerable value to the *Cypræa* or Cowry, as amulets or charms to prevent sterility; and among these shells were some of species from the Red Sea and Persian Gulf. A single specimen of another exotic shell (*Conus textilis*) must have been kept for its great beauty as an object of curiosity. All the shells used in the ornamentation of fountains, five in the city and one in the suburbs, are of species which still are common in the Gulf of Naples; these shells are separately distinguished and named.

The memoir forms a short but interesting chapter of Roman history, and it tells us more than is generally known about the habits of the former masters of the world. J. GWYN JEFFREYS

Banka und Biliton. Von Dr. E. Reyer. (Vienna, 1879).

IN this pamphlet, originally published as an article in the *Oesterreichischen Zeitschrift für Berg- und Hüttenwesen*, the author has brought together a vast amount of useful information on these two important tin-yielding localities. At the present time, when the trade in this important but sparingly-distributed metal has been almost entirely diverted from its ancient centres in Cornwall and Saxony by the development of the sources of supply in the East Indies and Australia, the valuable details contained in this pamphlet cannot fail to be read with much interest. By far the largest and most reliable part of the information on these districts is inaccessible to most readers, from the fact of its being written in the Dutch language, and Dr. Reyer has done good service in bringing together so much material in a compendious and available form. The geological structure of the districts, the distribution of the ore in them, the methods of working, and the mineral statistics of the two areas, are very fully described, and the monograph concludes with an interesting sketch of the life of the Chinese immigrants who are engaged in working these tin ores in the Malay Archipelago.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Greenwich Meteorological Observations

MR. BUCHAN (NATURE, vol. xx. p. 602) now admits that fundamental mean temperatures are to be found in Table 77. But his original unqualified remark (p. 526) was that mean temperatures for Greenwich "remain still to be calculated"; he even endeavoured to infer the mean annual temperature from the observations of the earth-thermometers, as though Table 77 (containing a value of this element with which no hitherto determined value for Greenwich can compete) had no existence. All this was likely to convey to an uninformed reader a very erroneous impression.

Table 52 contains simply a collection of the mean monthly results given in the twelve tables (38 to 49) referring to diurnal inequality, and as these numbers appeared to sufficiently well represent the varying temperatures of individual months, no account was taken of omitted days. But we can without difficulty determine their influence, usually small, in the months affected, and, in consequence of the now expressed want, shall probably take an opportunity of doing so. The question was of much greater importance as regards the fundamental values of Table 77, in forming which, as before mentioned, and as is

stated in the introduction to the volume, the influence of omitted days was duly taken into account, values for such days being adopted from the eye-observations (usually six daily) corrected for diurnal inequality by means of corrections derived from the discussion of the twenty years' photographs. Thus, among the twenty separate daily values on which each mean daily value in Table 77 depends, one or two may be derived from eye-observations in the way described.

The diurnal variation of temperature in the apartment in which the photographic barometer is placed is, on the average, less than one degree. WILLIAM ELLIS

Royal Observatory, Greenwich, October 27

Sun-Spots in Earnest

WITH reference to the fine group of sun-spots to which Prof. Piazzi Smyth draws attention in NATURE, vol. xx. p. 602, it may be interesting to mention that the incipient stage of the group in question is shown on two photographs of the sun taken at the Royal Observatory, Greenwich, on October 16 (two days before the date of Prof. Piazzi Smyth's observation). At that time the group consisted of three "veiled" spots and several very small specks hardly to be distinguished from the ordinary pores, together with small faculæ. No photographs were obtained on the next day, and on October 18 enormous changes had taken place, the "veiled" spots having developed into fine sun-spots, with nucleus and penumbra. Four photographs taken on this day show that changes were still taking place, and these continued throughout the remainder of the period of visibility of the group, viz., till October 21, when it passed off at the west limb. No trace of the group is to be found on two photographs taken on October 15, so that it would appear to have formed between October 15 and 16, and must have been quite in its infancy when first photographed on October 16, being then very nearly on the central meridian.

Several small spots have appeared on the sun lately, but they have been for the most part very short-lived. Thus a group of spots with faculæ, first seen on the east side of the sun on October 15, had completely disappeared on October 16. Another group consisting of six or seven small spots with faculæ, which appeared at the east limb on October 7, had completely closed up in the interval between October 10 and 15. On the whole the Greenwich photographs seem to support Prof. Piazzi Smyth's conclusion that the period of quiescence is now over, and that the solar activity is decidedly on the increase. W. H. M. CHRISTIE

Royal Observatory, Greenwich, October 25

THE Kew solar observations now are, unfortunately, limited to a daily inspection of the sun through a 3-inch telescope, and the drawing of a rough sketch of the spots on its surface, should any be visible, the object the Committee have in view being merely a continuation of the enumeration of the groups as they make their appearance, in the same manner as did Hofrath Schwabe.

I have referred to the sketches drawn on the 15th, 16th, 17th, and 18th instants, in order to see what records they afford of the outbreak of the group of spots mentioned by Prof. Piazzi Smyth in NATURE, vol. xx. p. 602, and find we noted on the 15th two small spots in the sun's northern hemisphere. These were not seen on the 16th, the disk being entered in the register as having "no spots," but at 10.30 A.M. on the 17th a group of small spots appeared to the south of the equator, just in the place occupied on the next day by the group of gigantic spots to which attention has been directed, allowance of course being made for the sun's rotation.

These observations show that the spots did not suddenly burst forth in their full grandeur, but that they broke through the sun's surface gradually, that is to say, the explosion, if such it was, extended over more than twenty-four hours.

In the examination of the Kew solar photograms from 1863 to 1872 now in progress here under the direction of Mr. De la Rue, we have found several instances of similar extensive changes in spots from day to day, not only in the eruption of large spots, but also in their closing up in an equally short space of time.

To give more recent instances, I find that a considerable group of spots was observed on June 28, of which we had no record on the 25th; and again, on July 11, some large spots were noted, whilst on the preceding day, July 10, "no spots" was entered in the register.

The magnetograph curves show a slight disturbance of the magnetic elements on the 16th and 17th, but during the 18th the needle simply recorded its ordinary daily range.

I trust that better-equipped observers will be able to give you more exact accounts of this interesting phenomenon. The sunshine recorder here indicated continuous sunshine on the 16th, occasional gleams on the 17th, and seven hours on the 18th, so the climate cannot be blamed for any shortcomings on the part of southern observers on this occasion. G. M. WHIPPLE

Kew Observatory, October 25

THE conclusion as to the increasing activity of the solar surface, drawn by the Astronomer-Royal of Scotland from his observations of a large solar spot on the 18th instant, is strongly confirmed by the present state of the south-east quarters of the sun's disk. Few prominences are now visible in the other portions of the limb, but on the 26th at 23° 10′ E. of the south point (direct image), the bright line C of the chromosphere extended to the height of 3′ 43″ from the limb, and this morning, the 28th, the greatest height was 1′ 17″ at 18° 46′ E. of S. On the 28th the remarkable prominences extended along the limb from—

18° 8′ E. of S. to 38° E. of S.,

and this morning they were traced from—

10° 51′ E. of S. to 20° 21′.

The ordinary level of the chromosphere does not extend above 5″ from the limb, but to-day it was rather over 6″.

Eight prisms of 60° were used in a Browning automatic spectroscope adapted to an 8-inch achromatic. S. J. PERRY

Stonyhurst Observatory, October 28

Wallace's "Australasia"

ALLOW me to thank the writer of the review in NATURE, vol. xx. p. 597, for some valuable criticisms of my book. It is quite refreshing after the common-place praises of most reviews to have one's errors pointed out and omissions noticed, and I hope to make use of such corrections in a forthcoming new edition. At the same time there are a few points on which I wish to say a word. In the first place the book is not a scientific work, but one of a series intended, as expressly stated, "for general reading." This is, of course, no excuse for errors, but it is a sufficient reason for giving *general* rather than detailed descriptions of weapons, canoes, &c., and for occasionally stating roughly the *size* of an article even when it varies greatly, in order to give definite ideas to readers who may be complete strangers to the whole subject.

I quite agree with my reviewer, that too much is included to be properly treated in one volume, but that was a matter dependent on the arrangement of the series, over which I had no control; and as I had in the earlier portion of the work overrun the space allotted me, I was obliged to restrict my notices of many parts of Polynesia, which is no doubt the most imperfect portion of the volume. It is here that the original work is most utilised, and it will be found that most of the passages criticised (including that in which I am charged with "becoming quite poetical") are Hellwald's. Of course, I should have corrected all his small inaccuracies, but it was almost impossible to do so without rewriting his work altogether. No doubt a very interesting volume could be written on Polynesia alone by the aid of the German authorities referred to by the reviewer; but when I state that the time allowed me for the composition of the entire work was six months, and that I actually completed it in eight, it will be seen that I was compelled to limit myself in the study of authorities as well as in the space I could devote to particular islands.

I think my reviewer forgets the character of the book as essentially geographical, when he objects to my treating New Zealand apart from Polynesia; hence I cannot admit the soundness of his criticism on the comparison of the characters of the Fijians and Polynesians, a comparison which, if I remember rightly, is that of an author who knew them both thoroughly—the Rev. G. Turner. I must also demur to the implication that land can never have extended where there is now a sea 2,000 fathoms deep. I suggest (p. 564) an extension of New Zealand as far as the Kermadec Islands as having possibly occurred "at some remote epoch," and I certainly fail to see its impossibility; yet this is what is suggested by my reviewer's remark, that unfortunately there is a depth of 2,000 fathoms between

them, and that such an extension "cannot therefore have existed." Moreover, the beautiful map of ocean depths with which the volume is illustrated shows a somewhat less depth than 2,000 fathoms on a slightly curved line between the islands, and I believe about the same depth exists between Madagascar and Africa, which have certainly at one time been joined.

There are some other matters touched upon on which I still venture to differ from my reviewer, especially as to the marvellous character of the Easter Island and other remains, and as to the value of the substitution of more for less liberal sectarian teaching in the Sandwich Islands; but on these points I have quoted authorities of considerable weight, and I leave my readers to form their own opinion. As to all matters of fact, I gladly accept correction from one who evidently writes with the advantage of a personal acquaintance with most of the countries referred to in his article. ALFRED R. WALLACE

Climatal Effects of Eccentricity

I AM grateful to Dr. Croll for noticing my letter. But I continue to think that if what seems to me to be the fundamental proposition of his theory, and which I quoted at the beginning of my former letter, be correct, and if the manner in which he and his reviewer have applied it be likewise correct, then we ought to find those differences in the *air* temperatures which my equations indicate. I say air-temperatures, because in Dr. Croll's theory changes of climate are referred to the varying distance of the sun, and climate depends on the temperature of the air.

The heating effect of the sun, other things being equal, has been hitherto assumed to be proportional to the excess of the temperature of the place above the temperature of space. A remarkable result which Pouillet had arrived at, and of which I was not aware when I wrote, shows that this method is incorrect. And I believe that what follows will to some extent afford a reply to the question which I have propounded, and at the same time have a proportionate bearing on Dr. Croll's theory. I quote Pouillet's words from the translation in Taylor's "Scientific Memoirs," vol. iv. p. 83.

"The total quantity of heat which space transmits in the course of a year to the earth and to the atmosphere . . . . would be capable of melting upon our globe a stratum of ice of 26 metres thickness. We have seen that the quantity of solar heat is expressed by a stratum of ice of 31 metres. Thus, together, the earth receives a quantity of heat represented by a stratum of ice of 57 metres; and the heat of space concurs in this for a quantity which is five-sixths of the solar heat. Between the tropics the heat of space is only two-thirds of the solar heat; for the latter is there represented by a stratum of ice of 39 metres."

These surprising results arise from the unequal absorption exercised by the atmosphere upon the heat rays proceeding from the stars and from the earth respectively.

It appears then, that, in applying Dr. Croll's proposition, we ought not to use the value of the temperature of space in forming our proportion, but we ought to use the temperature which the surface of the ground would assume were the sun extinguished. This Pouillet puts at $-89°$, or $-128°$ F. The substitution of 128 for S., instead of 239, reduces my calculated difference between the January and July temperatures at the equator to 11° F., *i.e.*, by about one-half.

If we make the same correction in the case, the high eccentricity at aphelion, for which the *Quarterly Reviewer* has calculated the January temperature of England, and found it 3° F. (I make it even lower), the new temperature comes out 17° F., which can hardly be thought low enough to cause any extreme difference from the present climate. O. FISHER

October 25

THE statement quoted by Mr. Fisher from Dr. Croll (NATURE, vol. xx. p. 577) that "the temperature of a place, other things being equal, is proportional to the heat received from the sun," is based on the assumption of Newton's law of cooling, viz., that the rate of cooling of a body is proportional to the excess of its temperature above that of the surrounding medium. This is approximately true only when the excess is small. When the excess becomes large the rate of cooling augments much more than in proportion. The amount of heat which must be supplied to a body in order to maintain it above the temperature of the surrounding medium is proportional to what would be its rate of cooling. Hence this amount increases as the excess of temperature increases—proportionally while the excess remains small, but much more than proportionally when it becomes large. Conversely, the temperature increases more slowly than the amount of heat supplied, and any variation in the supply will affect the temperature produced in a degree which is less for a large excess than for a small one, and, therefore, less than Newton's rule would give. The excess of the earth's mean temperature above that of space is large, and consequently calculations of changes based on Newton's rule must be in excess of the truth.

The formula obtained by MM. Dulong and Petit (Stewart on "Heat," Art. 235) from the rate of cooling of a thermometer-bulb *in vacuo* makes the necessary supply of heat proportional to $(1{\cdot}0077^t - 1)$, where t is the excess of temperature in Centigrade degrees. If we apply this to the case of the earth, and take 80° F. as temperature at the equator when the earth is at its mean distance from the sun, then the resulting temperatures at its greatest and least distances with our present eccentricity, are given as about 74° and 85° respectively. The fluctuation, which Mr. Fisher makes 21°, is reduced to about 11°. The fall in temperature which would follow a stoppage of the Gulf Stream is made by Newton's rule 59° ("Climate and Time," p. 36): the more accurate formula reduces this to about 37°. Dr. Croll suggests that the temperature of space may be lower than is usually assumed (p. 37). If it be taken as absolute zero ($-459°$ F.) the fall would not even then come out much greater than 45° F.

Several of Dr. Croll's tables should be similarly modified; at the same time it would be scarcely correct to say that these changes "touch Dr. Croll's theory somewhat closely." They do not invalidate the general contention, that a diminution of the Gulf Stream must diminish the mean temperature of northern regions to a very serious degree. E. HILL

St. John's College, Cambridge, October 25

The Weather and the Sun

PROF. PIAZZI SMYTH in his communication to NATURE, vol. xx. p. 431, evidently infers that changes in the condition of the sun must needs affect every part of the earth in the same way, whereas we have many meteorological analogies, which favour the notion that totally *opposite* effects may arise in different parts of the earth from the action of the *same* primary causes. For example, it is generally assumed that the same tropical heat which gives the primary impulse to the desiccating north-east trade wind of sub-tropical latitudes, furnishes the energy which exhibits itself in the almost constant precipitation under the equator. Any variation in the degree of this heat, should consequently affect localities situated in the region of the trades, and the equatorial calm-belt, in a diametrically opposite manner. Moreover, the notion that the British and Indian rain falls vary together now is altogether inconsistent with the well-known want of similarity between them, both as regards seasonal distribution and annual quantity in the past. It is also remarkable that while the present deluge both here and in India is traced to the sun's "*recovering* his forces and beginning already to shine after his recent languid spotless years with increased radiation on the great oceans of the south," the rainfall of England between latitudes 50° and 55° N. reached a decided maximum in 1877, the year when the sun was, to adopt the favourite metaphor, affected with the most extreme languor, and has been very high all through the period of unusually marked spot minimum, from which we are but just emerging.

The following figures from Mr. Glaisher's reports will illustrate what I have just said.

Great Britain, Lat. 50°—55° N.

Years.	Rainfall in inches.
1875	34·04
1876	34·60
1877	38·55
1878	32·61

More valuable results will generally accrue to science if, instead of founding vague hypotheses on a fancied likeness between isolated weather conditions, at places where the prime meteorological factors act in a totally dissimilar manner; induction is made from results which are derived from trustworthy data, and anticipated by a knowledge of admitted physical principles. As an example of this latter kind, allow me to conclude this letter by exhibiting

to your readers a recently discovered regular secular period in one of the meteorological elements of Calcutta; a period too, (though this is at present a matter of secondary importance) which decidedly favours the reverse hypothesis to that entertained by Prof. Smyth regarding the variation of solar energy. The following figures have been worked out, and communicated to me, by Prof. S. A. Hill of Allahabad, and he has I believe given his conclusions from them and similar results, in a recent number of the Austrian *Zeitschrift für Meteorologie*, which, however, I have not as yet seen.

The table which follows, shows the annual range of mean monthly barometric pressure at Calcutta, from 1840 to 1878 inclusive, bloxamed in a series of eleven years, the average length of a sun-spot cycle, beginning with the year of sun-spot minimum.

Calcutta.

Years of cycle.		Annual range of mean monthly pressure in decimals of an inch.
11	Years of minimum sun-spot	·530
1		·549
2		·538
3	...	·510
4	...	·499
5	Years of maximum sun-spot	·502
6		·502
7	...	·500
8	...	·506
9	...	·512
10	...	·514
11	...	·530

The figures for Roorkee, from 1864 up to the present time, give a similar result. So far then as we have gone at present in India, we find years of few sun-spots characterised by higher temperatures, greater wind-velocity, and greater range of barometric pressure than those of many spots. The terrestrial effects of a "languid" sun are therefore strikingly like those of an unusually *hot* sun.

Grosvenor House, Tunbridge Wells, October 18

Colour-Blindness

WHILE the subject of colour-blindness is before your readers, the present seems a favourable opportunity for calling attention to a method of experimenting which I used some years ago[1] for testing normal vision, and which seems, if applied to colour-blind eyes, likely to be capable of telling us something of the nature of that peculiar form of colour sensation.

When I made my experiments on normal eyes I intended extending the investigation to colour-blind eyes, but most unfortunately I was quite unable to find a true case of colour-blindness. All the cases reported to me proved, on examination, not to be produced by colour-blind eyes at all, but to be the result of want of observation and knowledge, as they all could distinguish between different colours, when placed alongside each other, and could also arrange the different colours, though when shown colours separately they made dreadful mistakes in naming them.

The method adopted in my experiments was as follows:—A prismatic spectrum was produced by passing a beam of light through a slit, a lens, and a bisulphide of carbon prism, in the usual way. The spectrum was thrown on a large number of rectangular reflectors, placed close to each other, and all capable of being moved so as to throw the light reflected from them to any point on a screen in front. With this apparatus we have the means of testing what colours can be produced by mixing others, and what colours cannot be so produced—by throwing the light reflected by one of the reflectors on the screen and trying if it is possible to match it by combinations of rays from other parts of the spectrum. It is found that for the normal eye the same sensation which is produced by the yellow part of the spectrum can be produced by mixtures of rays from the red and green parts, and also by rays from parts lying between these colours and yellow. And that the sensation which we call blue, can be produced by the blue part of the spectrum or by mixing rays from each side of the blue, that is by mixtures of violet and green. The yellow and blue are, however, the only two parts of the spectrum, the sensation of which can be imitated by combining rays from other parts of the spectrum. We cannot, for instance, produce green by any mixtures of rays from other parts of the spectrum. The red and the violet sensations are also incapable of being produced by mixtures.

[1] *Proceedings* of the Royal Scottish Society of Arts, 1871-2.

These results are, to a certain extent, a proof of the threefold nature of our colour sensations. And they also show us that it is a mistake to talk of colours as simple and compound, as all the colours we find in nature are compounded of rays of many different rates of vibration. The difference between different colours is, those of one rate of vibration, say those of the D-line, even though absolutely pure, are capable of exciting a compound sensation, namely, the red and green, while mixtures of rays from each side of the line B, are only capable of giving rise to a simple sensation—namely, the red.

Supposing this three-sensation theory to be true, then there are certain conceivable variations of it which would give rise to colour-blindness. The blindness, for instance, might be produced by two of the three sensations being very similar. This does not seem improbable when we consider that, to any two persons, with normal eyes, the different colours will not necessarily appear equally different, and that, in the same normal eye, the different simple sensations are not separated by equal differences from each other. That is, supposing our sensations of the three primary colours to be represented by the three angles of a triangle, then the triangles, if drawn to the same scale, would be of different sizes for the eyes of different persons, and for almost all eyes the triangles would not be equilateral. The side between the green and the violet would be shorter than the other two, because the sensation of green is more similar to the sensation of violet, than green is to red or red is to violet. Or we might conceive the colour-blindness to be produced by the different sensations being irregularly, or by being too widely, distributed over the spectrum. If, for instance, the green sensation extended into the red part of the spectrum and the red sensation into the green part, that is, if the same rays excited both sensations in the same proportion, not only in certain parts, but throughout their entire range, then an eye, so constructed, would be incapable of distinguishing red from green. Another way in which colour-blindness might result, is by an absence of one of the three sensations.

It is impossible, without experimenting on colour-blind eyes, to say whether any of these, or some other, is the true cause of colour-blindness, and it is very desirable that some one, accustomed to make colour observations, would test colour-blind eyes in the way suggested; it would settle at once, for the particular eyes experimented on, whether they are badly defined trichroic eyes or are dichroic. If the eyes are dichroic, then, clearly, there will be only one part of the spectrum, the sensation of which can be produced by mixtures of rays from other parts, and not two as in trichroic vision.

Besides the apparatus described many others, more accurate, might be constructed, but the great advantage of this arrangement is, that it is suited for testing eyes not accustomed to make accurate observations or to be trammelled with elaborate apparatus. If Prof. Pole was to undertake the investigation, he could easily devise some simple apparatus to suit the experiments which, in his hands, would probably give some valuable results.

Darroch, Falkirk, October 7

JOHN AITKEN

Subject-Indexes to the Royal Society Catalogue of Scientific Papers

As you have opened your columns to Mr. Garnett's valuable paper on "Subject-Indexes to Transactions of Learned Societies," you will perhaps allow me to make a suggestion in regard to the proposal contained in it. The initial objection to Mr. Garnett's scheme appears to me to be that the work he suggests will really be as large as the original catalogue, and, in fact, the same work in a new order. Even were it possible to get the money (probably little short of 10,000*l.*), the question would naturally arise whether or no the result was likely to be worth this great outlay. Moreover, the plan proposed by Mr. Garnett would not meet the great difficulty of compilation, which consists in the getting together of papers treating of identical subjects, but written with various titles by different persons. This would make it necessary to employ experts in each subject, and also a general practical editor for the whole, under whose eye all entries must pass. I cannot help thinking, therefore, with Mr. J. B. Bailey (p. 580), that the titles of the papers would have to be generally ignored.

If the index were made as indexes to catalogues are usually compiled, it might be got into at least a third of the space of the

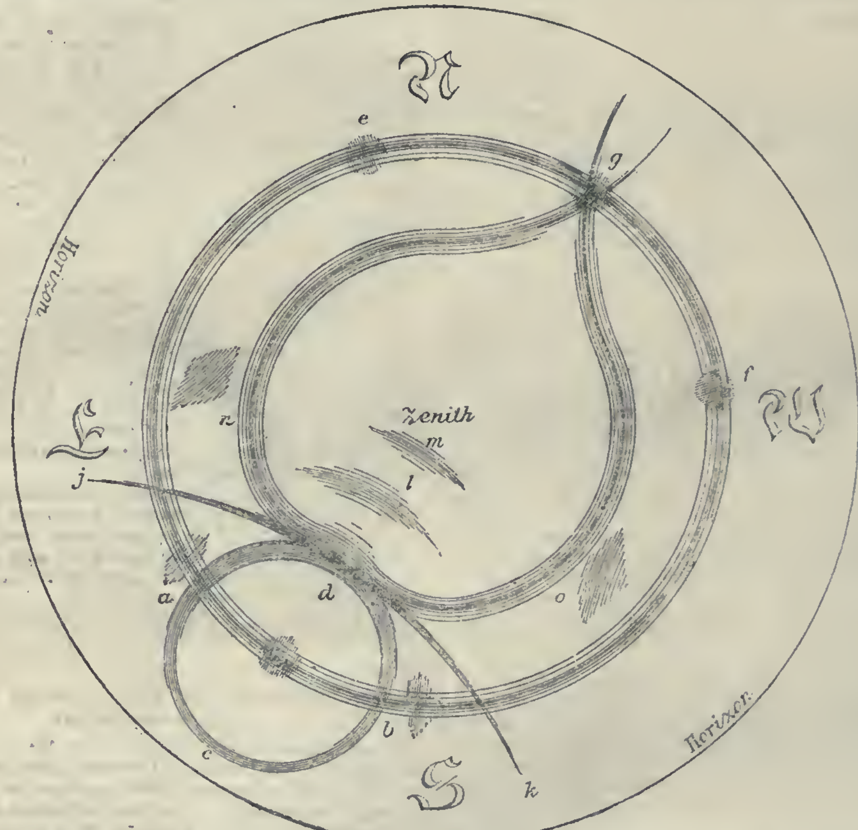
original book, perhaps into a sixth. As to the need of such an index there cannot be two opinions. If, however, a fuller classified catalogue, such as is proposed by Mr. Garnett, be thought necessary, would it not be better to make it in the form of a series of indexes of separate subjects? The day for great encyclopædic works is nearly past, and as the astronomer cares little for the papers of the zoologist, and would find them only in his way, so both the zoologist and the astronomer would wish to have his own subject in a distinct volume.

This leads me to the chief point of this letter, which is to draw attention to the work that is already being done. I have received a letter from Prof. Holden, of the United States Naval Observatory, in which he announces to me, as Secretary of the Index Society, his intention of making an index to all the entries referring to astronomy in the Catalogue of Scientific Papers, and also informs me that Prof. Abbe, of the United States Signal Service and Weather Bureau, has a complete card catalogue of the meteorological entries in the Royal Society Catalogue. Probably other workers have done the same for other subjects. This is, I think, the best use to make of the Catalogue of Scientific Papers, which is of immense value, in the first place as a catalogue of authors, and secondly, as a collection of anthentic documents from which a series of subject-indexes may be drawn.

Society of Arts, October 28 HENRY B. WHEATLEY

Solar Halo

I INCLOSE a sketch of a remarkable solar halo and parhelia which I observed here on the 22nd ult. As I happened to have facilities at hand, I was enabled to take the dimensions and position of the various features of the phenomenon with sufficient accuracy. These appearances were first seen by me at 9.30 A.M., and continued nearly constant in brilliancy till about 10 A.M., when they gradually faded, and at 10.30 hardly anything was visible except the outer ring, *abefg*, which continued till 1 P.M. At 9.45 the inclosed sketch was made and the measurements taken. The sun had then an altitude of about 30°, and was very misty and indistinct. It was surrounded by an ordinary solar halo of about 45° diameter; and through the sun passed another perfectly unbroken circle whose centre was exactly at the zenith. This circle had no colour and was similar in character to the ordinary concentric solar halo; its angular diameter was 120°; concentric with this was another circle of 78° diameter. This inner circle was not quite perfect at the point where the circle, *abcd*, touched it; it was slightly distorted, and through the same point (*d*) passed a portion of another circle of larger radius, *jk*. The junction of these three circles formed a beautiful spectrum, and was the most brilliant



part of the whole phenomenon. The inner circle was also imperfect on the side opposite the sun, when it branched off in two opposite curved tails, which, crossing the outer circle at the same spot, *g*, formed a mock sun. Two other mock suns were to be seen at *e* and *f*, 50° to each side of *g*. These three mock suns were all colourless, but at *a* and *b*, not on the concentric halo, but about 2° outside it, were two beautifully coloured mock suns, each being a perfect spectrum.

Finally, two portions of coloured circles were seen at *l* and *m*, with the concave side towards the sun, and two others at *n* and *o*, with their convex sides towards the sun, but in every case (both of circles and mock suns, *a* and *b*) the red colour was nearest the sun and the blue farthest from it.

I may mention, to give an idea of the brilliancy of the phenomenon, that many persons mistook one or other of the coloured bands for rainbows, and in one case one of the mock suns was supposed to be the sun itself (the sun happening to be hid from the observer by some adjacent buildings).

Dublin, October 11 HOWARD GRUBB

Karl Friedrich Mohr

IN your notice on the late Karl Friedrich Mohr there is no mention made of one of his most remarkable works, "Die Geschichte der Erde," the first edition of which appeared in 1866. In it he takes up what he considers entirely new ground

and certain of his chapters are in the highest degree interesting. His chapter on the origin of coal is perhaps more interesting than any other, and is full of suggestive reasoning. I have not seen the work cited in any of our treatises on geology, and yet the opinions of such an eminent chemist must have some weight in the treatment of problems wherein chemistry alone can furnish a satisfactory solution. J. P. O'REILLY

Dublin, October 22

Suicide of Scorpions

THE self-destruction of the scorpion when hard-pressed is unquestionable. I have on several occasions invited sceptics to witness the tragedy (!) in this part of Europe.

The scorpion we frequently meet with in and about "Sierra Morena" under stones and in crevices, is a large light-brown species often more than *two* inches from head to sting.

Having procured one I have placed it in a circle of glowing charcoal embers a foot or so in diameter; after vain attempts to get away it raises its tail over its back, pierces its head with its sting and dies, precisely in the way described by Dr. Thomson (NATURE, vol. xx. p. 577). F. GILLMAN

Provincia Jaen, Linares, Spain, October 20

Superficial Earthquakes

CAN any correspondent oblige me with an explanation of the following facts? The earthquake which took place at Virginia City some time ago was not felt by the workmen in the mines. Some years ago a much more violent earthquake shook the town, breaking chimneys, overthrowing houses, and so on. But it was hardly to be noticed in the mines; indeed, not at all in the deeper shafts. E. BURKE, Jun.

October 16

Coloured Lightning

ABOUT 4 P.M. to-day we had a pretty severe thunderstorm, accompanied by heavy rain, and the entire heavens were overcast by one unbroken cloud; three or four flashes of lightning were of a distinct blue colour, and then followed a flash of beautiful rose colour, succeeded by more flashes of blue lightning. Will some of your correspondents explain the cause of change of colour? and oblige A CONSTANT READER

Welland, Ontario, Canada, September 28

"MEMORIA."—The correspondent who signs herself thus must send her name if she wishes her letter to be inserted.

OUR ASTRONOMICAL COLUMN

THE SATELLITES MIMAS AND HYPERION.—The following are approximate times of the greatest western elongations of *Mimas* during the first week in November:—

	h. m.		h. m.
Nov. 1 ...	14 24 G.M.T.	Nov. 4 ...	10 15 G.M.T.
" 2 ...	13 1 "	" 5 ...	8 52 "
" 3 ...	11 38 "	" 6 ...	7 29 "

Observations of *Hyperion* during the present opposition are required before a reliable ephemeris of this satellite can be furnished. The true motion of the peri-saturnium is yet doubtful, unless Prof. Asaph Hall has been able to decide upon it from later observations than have been published. As we have stated before, Mr. Marth some years since conjectured that it might be as great as $+75°$ annually, and this rate of motion accords with Bond's determination of the place of the peri-saturnium in 1848 and Hall's results from Mr. Lassell's observations in 1852, and his own in 1875. So far as we know the Washington measures of 1878 are not yet published; probably they may throw more light upon the subject.

ANUARIO DEL OBSERVATORIO DE MADRID.—The seventeenth volume of this compilation (for 1879) reaches us late in the year. It is one of those useful compendiums of which the *Annuaire du Bureau des Longitudes* is probably the oldest, and may be taken as the type. Astronomical phenomena and details occupy a considerable space, and the volume is therefore fitly noticed in this column, but there is a great amount of miscellaneous information, geographical, meteorological, physical, and otherwise, which will recommend it to a larger class of readers. We remark some few points to which exception might be taken on the score of want of accuracy or completeness; thus the independent discovery of *Hyperion* by Mr. Lassell is not recorded, and the number of Uranian satellites is set down as eight, though four are queried with good reason. The discovery of Tuttle's comet is dated in 1858, no mention being made of its appearance in 1790. It is doubtless through a misprint that Encke's comet is stated to have appeared in 1695. Many of the miscellaneous tables are very full, as, for example, those of the altitudes of mountains in all parts of the world, the length of rivers, and the meteorological conditions in various parts of the peninsula, and as regards Spanish science, &c., the volume is no doubt to be considered authoritative. There are many who have occasion to consult works of this kind, who may like to have their attention directed to the present publication of the Royal Observatory at Madrid.

A NEW PRIVATE OBSERVATORY.—Observatories erected, equipped, and maintained in activity by private individuals are numerous in this country, and, as will appear from Prof. Holden's recent report, there are many of them in the United States; but the number of known observatories of this class upon the continent of Europe is not great, and the more interest therefore attaches to the addition of a new one to the list. Dr. Jedrzejewicz gives some account of an observatory he has constructed at Plónsk, about 37 miles from Warsaw, or in lat. 52° 37′ 39″, and long. 20° 30′ 59″ E. of Greenwich. The principal instrument is an equatorially-mounted refractor by Steinheil, of 6·4 inches aperture, to which are attached filar and other micrometers, and a spectroscope. Acting upon the advice of Dr. Vogel of Potsdam, Dr. Jedrzejewicz has the intention of devoting his time mainly to the measurement of double-stars, selecting such objects as are well within the power of his telescope; indeed, he has already made a considerable advance in this direction, having secured 860 complete observations of 170 double or compound stars, the result of some 8,500 separate measures, and with the view to enable astronomers to judge of the amount of confidence to be placed in the observations that may be published from Plónsk, he has given a comparison of his measures of a number of stars, which do not exhibit change, with those of Struve and others, and the comparison will tend to induce reliance upon his work. One remark we may make which bears generally upon the selection of objects for measurement with such an aperture as Dr. Jedrzejewicz possesses: it appears to have been too much the custom with the generality of observers who devote themselves to double-star astronomy, to accumulate a large number of measures of well-known, we may almost say, historical binaries, to the neglect of other objects, equally within the scope of their instruments, and equally deserving of attention. A carefully-considered list of stars is an essential in the actual state of this branch of the science, if the labours of the observer are to possess their utmost attainable value, in the future. The numerous discoveries of Mr. Burnham in particular confirm us in this view; his various lists exhibit many stars which it is highly desirable to keep under observation, and which do not yield in point of interest to other better-known binaries.

GEOGRAPHICAL NOTES

THE Japan papers report, with expressions of great regret, the loss, of which we have already had news by telegraph, of the *A. E. Nordenskjöld*, the little vessel

which M. Sibiriakof fitted out for the relief of the *Vega*. The vessel left Yokohama on August 1, and was lost on August 5, near Nemora, at the north-eastern point of the island of Yesso. The *A. E. Nordenskjöld* was commanded by Capt. Sengstake, an Arctic explorer of repute, who, when called to this duty, had arranged to accompany Dr. Otto Finsch in his expedition to the Pacific. The crew consisted of picked Arctic sailors, and there were also on board M. Gregorief, representing the Russian Geographical Society, and Herr Dankelmann, of Leipsic, the delegate of the Bremen Society. All on board were saved and were stated to be returning to Yokohama.

DR. OSCAR LENZ will shortly start on a tour to Marocco by order of the German African Society.

Les Missions Catholiques has published, in its last two numbers, some notes on Assam and the neighbouring countries, which have been furnished by a Roman Catholic missionary. By a singular coincidence the second instalment, containing an account of the Naga tribes, appeared just at the time when news arrived of Mr. Damant's murder in the Naga Hills.

THE new *Bulletin* of the Société de Géographie Commerciale, of Bordeaux, contains a paper of some interest, by M. G. Revoil, entitled "Le Pays des Çomalis-Medjourtines," which is accompanied by an outline map of that portion of Africa.

THE members of the Geographical Society of Algiers held their first meeting in the Hotel de Ville of that city on October 22, to elect their officers.

THE just-published *Bulletin* (for August) of the Paris Geographical Society, contains the itinerary of the Abbé Desgodins, of his journey from Pa-tang to Ta-tsien-len and back in 1877, and an account of the journeys of Père Duparquet in South Africa, by the Abbé Durand. There are some interesting letters between Dr. Rohlfs, Dr. Stecker, M. Duveyrier, and M. Marié Davy, concerning observations made in North Africa by Dr. Stecker, on electrical and other natural phenomena.

MR. STANFORD has just published a large scale map of Japan, which forms probably the best map of the country now in existence. It has been compiled by Mr. Knipping, whose official position in Japan has given him exceptional advantages for obtaining the necessary material. He has used the native Japanese surveys, which we believe are wonderfully accurate, data collected during his own extensive journeys in the country, travellers' narratives, and consular reports. The map is on the scale of seventeen miles to an inch, and is creditable to author and publisher, and certain to prove useful to all who have dealings with the country.

MR. EDWARD F. SANDEMAN will shortly publish, through Messrs. Griffin and Farran, an account of his travels in South Africa, under the title of "Ten Months in an Ox Waggon; Reminiscences of Boer Life." A special feature of the book will be the description of the home life of the Boers and their chief characteristics, and it will contain half-a-dozen chapters of shooting experiences in the country to the far east of the Transvaal, with accounts of the various big game of that region. A visit to the gold fields is also described, and some account will be given of the life of the miners. The volume will contain a map of the country.

KEW GARDENS

IT is highly desirable that the public should be fully acquainted with the real objects of the establishment of which we have the annual report[1] before us, as a very imperfect impression on the subject is prevalent. That object is not simply to collect as many forms of vegetation as admit of cultivation, with a view to facilitate the studies of botanists, whether young or old, much less to make mere collections of plants without any ulterior view; but while its unequalled herbarium and diligent staff are enabled to promote botany as a science, it has in view the rational recreation of multitudes and the accompanying improvement in taste, from the familiarity with exquisite forms and combination of colouring, aided by the attendant prevalence of order in each department; while in an economic point of view there are facilities for the investigation of diseases which affect our commerce or manufactures, unequalled facilities of diffusing through our colonies productions which may prove of vast importance to their interests, inquirers at home being able at once, through the museum and its curator, to become acquainted with matters in which their factories are more or less concerned, and thus to obtain information which in many cases has proved the source of national advantage. At the same time there are great opportunities for young cultivators gaining such a knowledge of the structure and intimate nature of plants as will not only be useful to themselves and their employers, but which has a tendency to improve by example the numerous tribe of gardeners who are too often deficient in the very knowledge which is of the utmost importance to successful cultivation. The interchange of plants and seeds also is carried on to a great extent at Kew, which is now the acknowledged ultimate medium for all communications from abroad with reference to what may be called industrial plants. The mass of correspondence which is carried on in this very useful department is almost overwhelming. Amongst other things, india-rubber plants, coffee, and quinine-producing barks, have received peculiar attention, respecting which interesting details will be found in the report. The cinchona plantations, not less than those of coffee, are every day of increasing importance, much of which is due to our national establishment at Kew. Not only have pains been taken to introduce the most improved forms of the coffee-plant, but the disease which is ravaging the coffee-plantations in Ceylon has been diligently studied by Mr. Abbay, whose observations were commenced in Ceylon in company with Mr. Thwaites. The first step to combating with diseases is doubtless an efficient knowlege of their nature, and it appears that the observations of these gentlemen and Mr. Morris have been attended with success in the application of proper remedies. Full figures are given in the report of the structure and nature of the coffee mildew by Mr. Abbay. This is not the only good work which has been done at the new laboratory during the past year, where the writer of the present notice has more than once profited by the facilities which it affords for observation.

It is not to be expected that the introduction of useful plants will be equally successful everywhere. Much depends on the intelligence and care of the recipients, even when there is no inaptability of climate. We anticipate in future reports that the diffusion of other matters less generally known will be recorded as at once successful and important. There is, perhaps, no set of plants of more importance than those which produce india-rubber. Attention was drawn years ago to the wasteful destruction of native plants and the necessity of greater care being taken with the forests in which these trees abound, and a committee was appointed for the furtherance of this object. The trees which produce this valuable substance are various, and belong to very different natural orders, and the extension of different sources of production, in consonance with different varieties of climate, has been a matter of constant anxiety at Kew. Here, again, a perusal of the report before us will be highly instructive.

Besides the matters above mentioned, at the close of the report many suggestions of sources of possible utility are given, which will be read with much interest, amongst which we may mention the Rain-tree of Peru, the South

[1] "Report of the Progress and Condition of the Royal Gardens at Kew during the Year 1878."

African Bamboo, the Sugar-Cane Disease, Substitutes for Vegetable Ivory, and Paper Materials.

As regards the plants under cultivation, it should be stated that great pains are taken to name them conspicuously and correctly, a matter of extreme importance to students, and one which every day engages the unwearied attention of the staff at the Herbarium. Without almost unlimited means the collection could scarcely be much extended. The admission, however, of Mr. Peacock's unequalled collection of succulent plants for a limited but sufficiently extended period should not be passed without notice. The proposal was a happy one, and the acceptance much to the credit of the authorities. The groups of hardy economic plants and of those of a similar character which require a higher temperature than our country can offer are of especial interest to the student. The plants of peculiar botanical importance which have flowered during the past year are duly recorded, while an especial report, accompanied by a figure, is devoted to a new tropical fodder-grass which grew and flowered under store treatment. At Singapore, Adelaide, and elsewhere the hopes conceived of it are very great, and seeds of it have been widely distributed from Kew. Nor are matters of cognate interest at home neglected. A notice is given of that form of the prickly comfrey which is likely to be a valuable fodder plant in Great Britain and Ireland. It seems to be a hybrid between *Symphytum officinale* and *S. asperrimum*; we have seen it lately in great perfection and in full usage, where it is greedily consumed by cattle, which thrive upon it immensely, while they will not touch the common comfrey.

The ravages of insects amongst plants are of no less interest than those which are produced by fungi. A very small bug, for example, is highly detrimental to the tea plantations in India, and Mr. McLachlan has given a great deal of valuable information on such subjects, information of such importance that the want is suggested of a consulting entomologist, at the disposal of the different Government offices, who should receive a retaining fee in return for investigating and reporting upon the various questions respecting which the residents in our various British dependencies apply for information.

At the commencement of the report there is a notice of the condition of the tropical fern house as regards the decay of the rafters, which the late storm has too sadly confirmed, and it is in consequence suggested that some hard wood like teak or blue gum should be substituted. The suggestion is one of great importance to all who are interested in the sustentation of their stoves and conservatories. Foreign deal is often dangerous. Every one who has watched the progress of decay in imported wood as used in railway construction, must have seen how soon they become infested with such fungi as *Lentinus lepideus*, *Trametes pini*, and *Lenzites sepiaria*, of course, from spawn contained in the wood. But home-grown wood is no less subject to decay from fungi. Where oak is grown from old stools, the wood is apt to have a tint, which, to persons well skilled in such matters is known as foxy. Such wood would at once be rejected in our naval yards, but we have seen a case in which it was used in the construction of a range of hothouses, where the whole in a few years was destroyed by *Dædalea quercina*; and deal, whether of home or foreign growth, is soon infested with *Polyporus medulla panis*, which is, we believe, a condition of one of our commonest fungi. It is not always possible to say whether any mycelium is present in wood; it is better, therefore, as Sir Joseph Hooker suggests, to use some material less liable to decay.

It remains only to notice the acquisitions to the herbarium during the past year. One of the most important is a collection of fungi containing more than 10,000 species, a great portion of which are typical. That of Mr. Dazell is important from its containing type specimens of the Bombay flora. Messrs. Cosson, Miers, and Casimir De Candolle have sent collections of greater or less magnitude and value, while the list of contributors either in specimens or drawings occupies more than three columns. The botanical publications prepared in connection with the work of the herbarium have been of an importance equal to that of former years, while the third volume of Hooker and Bentham's Genera now in the course of printing, is the result in great measure of last year's studies, which have never wavered.

M. J. BERKELEY

NORDENSKJÖLD'S ARCTIC VOYAGES[1]

NORDENSKJÖLD'S next visit to Spitzbergen was made in 1868, in a "small weak steamer" the *Sofia*. The main object of the expedition was to penetrate as far north as possible, but as we have said already it was not very successful in this respect. The other objects of the expedition included an examination of the flora and fauna of Bear Island, the single remaining fragment of an extensive polar territory which probably at one time connected Scandinavia with Spitzbergen, the flora and marine fauna of which was still almost unknown, though fitted to throw important light on the animal life not only of the Scandinavian peninsula, but also of the northern shores of Britain which are washed by the Gulf Stream; a careful examination of the strata on Bear Island and at Ice Fjord and King's Bay which contain fossil plants, and a search for post-miocene strata on the peninsula between Bell Sound and Ice Fjord, which might afford some information as to the transition from the warm climate of the miocene period, which produced a luxuriant forest vegetation, to the ice masses of the present time; a more thorough examination of the Saurian strata at Cape Thorsden; an examination of the fragments of skeletons of whales found on the shores of Spitzbergen; a continuation of the collection and examination of the land and marine fauna and flora; dredgings at the greatest depths; magnetic and meteorological observations; geographical determinations of position, &c.

It was on this occasion that a week's stay was made at Bear Island, which lies about half-way between the north coast of Norway and Spitzbergen, and of which we should have liked to see a map and some views in Mr. Leslie's volume. Some of the results obtained in this visit are thus given by Mr. Leslie:—"Bear Island forms a pretty level plateau, two to three hundred feet above the sea, rising here and there into inconsiderable elevations and furrowed by small valleys, in the bottoms of which little streamlets seek their way among the naked stones. In the south-east the appropriately named Mount Misery rises perpendicularly from the sea to a height of about 1,200 feet, and in the south the Fuglefjeld is about the same height. On neither of these, however, is there any glacier or perpetual snow. It is not the formation of the island which gives it so desolate and forbidding an appearance, but the monotonous grey colour of the whole landscape. No trace of any grass turf is to be found in the interior, far less of any trees or bushes; only the Polar willow (*Salix polaris* and *herbacea*) with its thread-like stalks creeping in the moss, and two or three leaves, scarcely the size of a finger-nail, raised above it. Green patches in hollows where water has collected and formed a sort of marsh consist principally of mosses with scattered specimens of the Polar ranunculus (*Ranunculus sulphureus*) and a few other plants and grasses sparingly mixed with them. Except in these marshy places, the ground is nearly everywhere without the slightest trace of covering. By the combined action of water and frost the rocks have been literally frozen

[1] "The Arctic Voyages of Adolf Erik Nordenskjöld, 1858–1879." With Illustrations and Maps. (London: Macmillan and Co., 1879.) Continued from p. 611.

asunder, the limestone to small angular fragments, and the sandstone to larger or smaller blocks heaped one upon another. Such collections of stones cannot of course afford nourishment to higher plants, the more especially as any little mould that may be formed is immediately swept away by the wind or washed away by the rain. At long intervals in this wilderness of gravel and limestone there are found solitary specimens of the Arctic poppy (*Papaver nudicaule*), *Saxifraga*, *Draba*, *Sagina*, &c. Lichens, especially the larger species, occur here very sparingly and badly developed, though in spots the ground is almost covered by species which are exceedingly rare in the flora of Scandinavia. Where sandstone is the prevailing rock, the view is still more unpleasing. There is a considerable extent of surface where the only method of progression is by jumping from one block of stone to another, from which blocks all the higher plants, with the exception of a grass or two, are banished. The exterior of the island is more attractive. The rocks rise perpendicularly out of the sea, and as they consist of the looser formations, they have, in course of time, been shaped by the waves into the forms of arches, grottos, towers, columns, &c. The projecting rocky promontories are in some places found to be clothed with turf, and the perpendicular cliffs are richly hung with luxuriant *Cochlearia*.

II.

III.

I. Inland Ice (A) extending into the Sea (D) and terminating in a steep front, 100 to 200 feet high. II. Inland Ice abutting on the bottom of an Ice-fjord, *i.e.*, a Fjord in which real Icebergs are formed. III. Inland Ice abutting on a Mud-bank.

"The explanation is easy. It is only the ledges where the sea-fowl sit that are thus ornamented, and it is only in the rich mould originating from these fowl that the plants can attain such luxuriance. This leads us to the most remarkable thing about Bear Island, its fabulous richness in sea-fowl. Indeed it may be said that the fowl are the proper inhabitants and owners of the island. There are, it is true, some mountain foxes, but they are very scarce, and the greater number only make a visit during winter, resembling in this the Polar bear, from which the island is named, as it cannot, at least now, support itself here in summer. During that season the walrus, which soon after the discovery of the island was found upon its shores in unheard-of numbers, and a little flock of which Keilhau had an opportunity of observing, is now sought for in vain. Even in winter, according to the latest observations, the Polar bear is an unusual guest here. . . . .

"The number of plants found by the botanists of the expedition was thirty-three, which, with the other five formerly observed, but not now found, makes the whole number of phanerogamous and higher cryptogamous plants found on Bear Island thirty-eight. The number of species of insects found was twelve. The number of marine animals was unexpectedly small in consequence of the unsuitable nature of the bottom. A great part of the island consists of strata belonging to the Mountain Limestone, in which are found in abundance mussel shells, corals, &c., showing that in times long past quite a different animal world lived in an almost tropical ocean. Two and a half centuries ago seams of coal were discovered on the north coast of the island, showing as black parallel bands on the perpendicular cliffs facing the sea. As the coal that occurs on Spitzbergen had been proved by the preceding Swedish expeditions to belong to the comparatively recent tertiary period, it had been considered probable that this was the case also with that found on Bear Island. But on examination being made impressions of plants were found, partly in the coal, partly in the sandstone separating the seams, which afforded indisputable evidence that the strata here belong to the true coal formation. Splendid *Sigillaria*, *Lepidodendra*, *Calamites*, and other characteristic fossils of the Coal period were taken, not without danger to life, from the perpendicular sea-cliffs on the north side of the island, and it was with deep regret that others had to be left behind because there was not time to cut them out of the rock."

Ice Fjord was again explored and much new geological data obtained, and various parts of the north coast examined. Of this expedition, the distinguished *savant*, Prof. Oswald Heer of Zürich, declared—"In my opinion

the Swedish Expedition, by the rich collections it has brought home, has achieved more, and more widened the horizon of our knowledge, than if it had returned merely with the information that the *Sofia* had hoisted her flag at the North Pole."

Nordenskjöld's last expedition to Spitzbergen was made in 1872-3, when a winter was passed in the island, with the intention of pushing north by the Seven Islands by means of sledges. As a preleminary to this, he paid a visit to Greenland in 1870, for the purpose of ascertaining

Glacier in Fair Haven.

the suitability of the Eskimo dog for sledging purposes. After careful observation Nordenskjöld came to the conclusion that reindeer were much better adapted to the work than dogs, and so it was decided to use the former in the contemplated expedition. While in Greenland Nordenskjöld made a journey of a few days into the interior and brought back some interesting results. He succeeded in penetrating only a distance of thirty miles,

Astronomical Observatory at Mussel Bay.

and that with great difficulty on account of the rough nature of the inland ice and the frequent crevasses that had to be passed.

"On the surface of the inland ice no stones were met with at a distance of more than a cable's length from the border; but everywhere there were to be found vertical cylindrical holes, a foot or two deep, from a couple of lines to a couple of feet in diameter and so close

to one another that it was impossible to find between them room for the foot, much less for a sleeping sack. . . . In these holes in the ice, filled with water and in no way connected with each other, Nordenskjöld found everywhere at the bottom of them, not only at the border but in the most distant parts of the inland ice which he visited, a layer some few millimetres thick, of grey powder, often conglomerated into small round balls of loose consistency. Under the microscope the principal substance of this remarkable powder appeared to consist of white angular translucent grains. There could also be observed remains of vegetable fragments; yellow, imperfectly translucent particles, with, as it appeared, evident surfaces of cleavage, possibly felspar, green crystals (augite), and black opaque grains, which were attracted by the magnet. 'The substance,' says Nordenskjöld, 'is not a clay, but a sandy trachytic mineral, of a composition (especially as regards soda) which indicates that it does not originate in the granite region of Greenland. Its origin appears to me, therefore, very enigmatical. Does it come from the basalt region? or from the supposed volcanic tracts in the interior of Greenland? or is it of meteoric origin? The octahedrally crystallised magnetic particles do not contain any traces of nickel. As the principal ingredient corresponds to a determinate chemical formula ($2R\dot{S}i^2 + \dot{A}\dot{l}\dot{S}i^3 + H$), it would perhaps be desirable to enter it under a separate class in the register of science; and for that purpose I propose for this substance the name Kryokonite (from κρύος and κόνις). 'When I persuaded our botanist Dr. Berggren, to accompany me in the journey over the ice,' he continues, 'I joked with him on the singularity of a botanist making an excursion into a tract, perhaps the only one in the world, that was a perfect desert as regards botany. This expectation was, however, not confirmed. Dr. Berggren's keen eye soon discovered, partly on the surface of the ice, partly in the above-mentioned powder, a brown polycellular alga, which, small as it is, together with the powder and certain other microscopic organisms by which it is accompanied, is the most dangerous enemy to the mass of ice, so many thousand feet in height and hundreds miles in extent. This plant has no doubt played the same part in our country, and we have it to thank, perhaps, that the deserts of ice which formerly covered the whole of northern Europe and America have now given place to shady woods and undulating cornfields. Of course a great deal of the grey powder is carried down in the

Canal in the Ice of North-East Land.

rivers, and the blue ice at the bottom of them is not unfrequently concealed by a dark dust. How rich this mass is in organic matter is proved by this circumstance among others, that the quantity of organic matter in it was sufficient to bring a large collection of the grey powder, which had been carried away to a distant part of the ice by several now dried-up glacier streams, into so advanced a state of fermentation or putrefaction, that the mass, even at a great distance, emitted a most disagreeable smell, like that of butyric acid.' "

The land gradually rose, and at their turning-point they had reached a height of 2,200 feet above the sea. During this visit to Greenland Prof. Nordenskjöld made some interesting observations on glaciers. "It is," he says, "a common error among geologists to consider the Swiss glaciers as representing on a small scale the inland ice of Greenland, or the inland ice which once covered Scandinavia. The real glacier bears the same relation to inland ice which a rapid river or brook does to an extensive and calm lake. While the glacier is in perpetual motion, the inland ice, like the water of a lake, is comparatively at rest, excepting at those places where it streams out into the sea by vast but short glaciers. If one of these glaciers, through which the ice-lake falls out into the sea, pass over smooth ground where the bottom of the ocean gradually changes into land without any steep breaks, steep precipitous glaciers are produced from which indeed large ice-masses fall down, but do not give rise to any real iceberg. But if the mouth of the fjord be narrow, the depth of the outlying sea great, and the inclination of the shore considerable, the result will be one of those magnificent ice fjords which Rink so admirably describes. No. II. in the diagram on p. 632 illustrates this more clearly.

"True icebergs are formed only in those glaciers which terminate in the manner indicated in No. II., though pieces of ice of considerable dimensions may fall from a steep precipice (No. I.). These various kinds of glaciers occur not only in Greenland, but in other ice-covered polar lands, *e.g.* in Spitzbergen, though on so much smaller a scale than in Greenland that one never meets in the surrounding waters with icebergs at all comparable in magnitude with those of Davis Straits.

"In Spitzbergen, and probably also in some parts of Greenland, the ice passes into the sea, as in No. III.

It was in this expedition that Nordenskjöld obtained

the two famous meteors, one of which, weighing nineteen tons is now in the Riks-Museum at Stockholm, and the other, nine tons, in the Museum of Copenhagen.

For the expedition of 1872-3 the Swedish government provided a steamer, the *Polhem*, and a brig, the *Gladan*, which were accompanied by the *Onkel Adam* as tender. Tromsö was left on July 30, and Ice Fjord was again visited, where a search was made in Coal Bay. Some little time was spent at Fair Haven, on the north of the island with the view of finding the place where the Dwarf Birch had been discovered in 1870 by Nathorst and Wilander. After a long fruitless search, and when all hope of finding it was given up and the return to the boat commenced, its dark green leaves were at last observed projecting from the surrounding moss. The dwarf birch found here, the *Betula nana, var. relicta*, TH. FRIES, is believed to be a survival from the time when Spitzbergen possessed a finer and warmer climate than now. Its height, as found here, did not exceed two feet, the thickest stem being from two to three lines in diameter. After the return to Sweden it was found by the help of the microscope that a stem of this thickness was about eighty years old. The yearly rings were exceedingly thin and faintly marked in several specimens, and in some parts of the stem, altogether indistinguishable. A well grown beautifully flowering specimen of the *Cardamine pratensis* also rewarded the search of the botanist, a *find* which was specially welcome, because this plant, though pretty widely distributed, is seldom found in flower on Spitzbergen.

Leaving Green Harbour on August 4, the *Polhem* proceeded on her voyage with the *Gladan* in tow, passing through the sound between Prince Charles Foreland and the mainland and anchoring on the 7th in Fair Haven for the purpose of regulating the chronometers at the place where Sabine and his companions spent three weeks in 1823, carrying on a series of physical and astronomical observations. The place which is situated on the south-western shore of the inner Norway island still bears the name of Sabine's observatory, and is distinguished by a great number of stones collected in a circle. While here, Wijkander carried on a series of magnetic observations at Sabine's observatory. Astronomical observations were also made, and two and sometimes three boats were at work dredging from morning till night. It ought also to be mentioned that on the drift-ice which the *Polhem* had encountered a short time before, Nordenskjöld had found small quantities of dust similar to that which he had discovered in the snow during a snow-storm at Stockholm in December 1871. This dust, which he believes to be of cosmic origin, contains metallic iron, cobalt, nickel, phosphoric acid, and a colloid organic substance. "However small and inconsiderable the quantity of this substance may be in proportion to the snow or water falling at the same time," he writes, "it may yet play an important part in the economy of nature; for example, by means of the phosphoric acid which it contains it may restore the fertility of the soil impoverished by repeated harvests. This observation ought also to be of great importance for the theory of meteors of the aurora, &c. Perhaps we should inquire whether in this phenomenon we are to seek the explanation of the abundance in which magnesia, which occurs plentifully in meteorites, is found to exist in certain distinct geological districts, and if an increase of the earth's mass, which is certainly minute, but which is going on continuously, ought not to produce very considerable changes in the geological theories now prevailing, which proceed on the supposition that the globe is as nearly as possible unaltered in mass since the first occurrence of plants and animals, and that the geological changes have always depended on changes of distribution in the mass over the surface of the earth, never upon the arrival from without of new constructive material for our globe."

While at Fair Haven the expedition was visited by Mr. Leigh Smith in his yacht, who promised that he would be among the first to look them up next summer. After a long enforced delay in Fair Haven on account of the ice, the expedition got away in September 1, but failed in every attempt to reach the Seven Islands. Mussel Bay, then, a small inlet off the east side of the mouth of Wijde Bay was chosen as the winter quarters of the expedition, and here all three vessels were ultimately locked in the ice. One large building was erected on shore besides magnetical, meteorological, and astronomical observatories. During the whole of the stay of the expedition here regular observations were carried on in their observatories. Provisions were short, and all had to be put on allowances; though scurvy broke out there was only one death, and altogether the winter was a dreary one, in spite of every effort to keep officers and men constantly employed.

Wijkander remained whole nights in his observatory bravely defying the cold and patiently overcoming the many difficulties attending astronomical observations made in such circumstances. In the cold weather the work out of doors was not stopped and the dredgings still went on, it being of great importance to ascertain whether the severe cold and the long darkness exercised any special influence upon the marine animal and vegetable world.

With the arrival of spring preparations were made for the ice-journey to the north, but as we have said already they did not get beyond the Seven Islands. Nordenskjöld makes some interesting observations on the rugged ice which prevented him attempting to push further northwards. "The ice we thus passed is formed not of colossal blocks or icebergs, but of angular blocks of ice, *not waterworn*, piled loosely over each other, so as to form pyramids, or walls of ice, up to thirty feet high, which were so close to each other that the space between them was frequently not large enough for our tent. The cause of the formation of these ice-walls, which were also observed by Wrangel on the north coast of Siberia, is probably to be sought for in the changes of volume which ice undergoes when its temperature is changed. According to Plücker and Geissler, the linear expansion-coefficient of ice is $= 0{\cdot}0000528$. If, therefore, ice of 0° C. be cooled to -15° C., cracks must arise which, for 1,000 metres, have a breadth of 32 inches. The cracks naturally freeze together immediately afterwards, and when the ice is again warmed, for instance to -5° C., a piling-up must take place of 21 inches per kilometre. During the course of the winter this phenomenon is repeated innumerable times, one layer of ice being piled upon another, till the whole ice-field forms a confused mass of blocks of ice heaped up against each other. Similar forces are also in operation in the crust of the earth, with less intensity, indeed, in consequence of the smaller expansion-coefficient of the rocks which compose it, and the inconsiderableness of the changes of temperature which occur in them, and the cracks thus formed may here come together again, provided no chemical or mechanical sediment has been deposited in them, as is, perhaps, often the case. On the other hand, the forces operate in the earth's crust during millions of years, and I doubt not that in the circumstances here noticed the cause of the strata being contorted, dislocated, *and thrown over each other* is to be sought for. This last, perhaps, to judge by the observations I had the opportunity of making on the polar ice, happens far oftener than we commonly suppose, and when it takes place there often occurs no considerable disturbance in the original horizontal position of the stratum. Certainly in most cases the veins filled with foreign minerals, by which the upper strata of the earth in particular are intersected in all directions, derive their origin from similar causes; that is

to say, from cracks which have in consequence of changes of temperature many times over opened and come together again, *provided they were not prevented by the falling in of débris*. This has, however, often taken place, considerable masses of sediments, formed chemically or mechanically, have frequently collected in the cracks, and during the immense duration of geological ages they have hardened and been metamorphosed to solid crystalline rocks—limestone, quartz, felsite, pegmatite, &c."

To make up for the disappointment of not being able to push beyond the Seven Islands, Nordenskjöld made a journey round the coast of North East Land, and right across the island from east to west. "North East Land," he tells us, "forms the most northerly of the four large islands, into which Spitzbergen is divided. Its extent from north to south is seventy-five and from east to west about ninety-two geographical miles. The whole interior is occupied by an ice-sheet 2,000 to 3,000 feet thick, to which the fall of snow (and rain) during summer and winter brings new material and which accordingly would be unceasingly increased, if the mass of ice did not, as is the case with all glaciers, flow out into the sea slowly but without intermission. The principal direction of the ice-stream in North East Land is towards the east, and the whole of the east coast is therefore occupied by a single precipitous ice-wall, insurmountable from the sea, which, being nowhere interrupted by rocky heights or tongues of land, forms the broadest glacier or skridjökel known to man. It is, for instance, considerably broader than the Humboldt glacier in Greenland described in such lively colours by Kane. Northwards, however, the ice-sheet of North East Land terminates with an even and gentle slope, which sometimes reaches the sea, but generally leaves a small stretch of ice-free land along the coast. On this side there is no obstacle to an advance into the interior, at least from precipitous slopes."

With regard to the glaciers which cover the surface of this island, Nordenskjöld writes :—

"Like the glaciers of Switzerland, of Greenland, and of Scandinavia, the glaciers of Spitzbergen are interrupted by clefts or fissures which often extend perpendicularly through the whole mass of ice several thousand feet thick. The occurrence of these fissures stands in close connection to the motion of the glacier, and there is therefore a smaller number to be met with where the glacier is spread over an extensive level field without interruption from rocky heights. Accordingly we had reason to suppose that clefts or fissures would not in any specially great number intersect the way we had chosen and I hoped besides that all the crevasses would have been filled with snow during the snow-storms of winter. This supposition was so far correct, inasmuch as fissures do not here occur in such numbers or of such size as in that part of the inland ice of Greenland which I examined along with Dr. Berggren in 1870—but deep almost bottomless openings do nevertheless occur in numbers sufficiently large to swallow up us and our sledges. They were the more dangerous as they were for the most part concealed by a fragile vault of snow, so that even when we stood on the edge of the cleft, it was only by boring with an ironshod stick, very often first by ourselves falling in, that we could assure ourselves of neighbourhood, direction, and extent."

In spite, however, of the innumerable concealed crevasses which they had to pass, the journey across the glacier-bound island was safely accomplished. The snow, he found, at a depth of four to six feet, passes into ice, being changed first to a stratum of ice-crystals, partly large and beautiful to the eye of the crystallographer, then to a crystalline mass of ice, and finally to a hard homogeneous glacier ice, in which, however, there could still be observed numerous cavities filled with air, compressed by the pressure of the overlying ice. When the ice-wall becomes on the melting of the ice too weak for the pressure of the inclosed air, these holes break up with a peculiar crackling sound, which in summer is continually to be heard from the pieces of glacier ice floating about in the fjords.

Many other extremely interesting observations were made on this journey as to the nature of Arctic land-ice. For example Nordenskjöld says :—

"In many respects there is a very essential difference between the ice-field over which we now travelled and the inland ice-field in Greenland, which was visited by me in 1870. The reason of this may perhaps be in a great degree the fact that in North East Land we wandered over a kind of *nevé region*, that is to say, over a part of the glacier where the surface is occupied by a layer of snow which does not melt away during summer, while in Greenland at the beginning of the month of July the snow upon the surface of the glacier was on the contrary already nearly completely melted. No trace of the glacier lakes, the beautiful and abundant glacier streams, the fine waterfalls and fountains, &c., which occur everywhere on the Greenland inland ice, could be observed here, and the configuration of the surface showed that such forms never occur, or only to a very limited extent. The melting of the snow clearly goes on upon Spitzbergen on too inconsiderable a scale for such phenomena to arise." Another curious phenomenon of this Spitzbergen ice was an area near Cape Mohn which was intersected by canals which for the most part ran parallel with each other, at some places at a distance of only 300 feet. The depth was up to 40 feet, the breadth 30 to 100. "Sometimes, also, there occurred other depressions, bounded in all directions by precipitous sides, of greater depth than the glacier canals, but of limited extent; these, perhaps, may most fitly be called by the name given them by the sailors—*docks* or *glacier docks*." With regard to the cause of these curious phenomena Prof. Nordenskjöld writes :—

"The inland ice of North East Land was at the time of our visit too much covered with snow for me to make out with complete certainty the way in which the glacier *canals* originate. That they were not river channels was clear. For they were much deeper than the river channels on the Greenland inland ice, where, however, the melting of the snow must proceed on a much more considerable scale than on Spitzbergen, and they occur in too close proximity at certain places (while at others they are completely absent) for them to be the beds of the channels of the streams, certainly very inconsiderable, which are produced here during the height of summer. There is a strong probability, on the other hand, that they originate from faults in the ice, strongly resembling those that are observed in the solid strata of the earth, and which, there as here, derive their origin from the alternate expansion and contraction of the strata or the ice in consequence of variations of temperature."

While Nordenskjöld was out on this sledge journey the work at Mussel Bay was still carried on. Soon after Nordenskjöld's departure Wÿkander commenced a series of pendulum observations. The tidal observations were also extended. Five minute observations were carried on at least a whole hour twice a day, at ebb and flood. After the long, dreary, and trying winter, our readers can easily imagine how welcome was the sight of Mr. Leigh Smith's yacht the *Diana*, steaming into the bay on June 12, with an abundant supply of much-needed comforts and luxuries.

From what we have written it will be seen that Mr. Leslie has been able to bring together from the wealth of material which exists on these various expeditions of Prof. Nordenskjöld, enough to render his volume one of general interest and great scientific value. We need not follow him in his narrative of Nordenskjöld's two journeys in 1875 and 1876 to the mouth of the Yenissei, for the purpose of proving that a sea-route from Europe along the north

coast of Europe and Asia was perfectly practicable to that river. Some of the scientific results of these expeditions were published in NATURE at the time, and it is well known that so far as the immediate object was concerned the expeditions were completely successful. Full details will be found in Mr. Leslie's volume. From what we have said it will be seen that comparatively young as Prof. Nordenskjöld is, he has done an amount of work rarely accomplished even in a long lifetime. Appended to Mr. Leslie's volume is a long bibliography of the published results of these expeditions of Nordenskjöld, and from this it is evident that they have borne rich fruit in nearly every department of science.

HERING'S THEORY OF THE VISION OF LIGHT AND COLOURS[1]

II.

BEFORE propounding his theory, the author thinks it necessary to devote one memoir—the fourth—to an essay, the object of which is to define clearly the nature of the sensations of black and white and their mixture gray. He remarks that it is a habit to treat visual sensations rather according to their physical origin than by their own nature; and this peculiarly influences the ideas entertained about the sensations of black and white. We know that physically, white light is a combination of rays of all wave-lengths, and we have no physical notion of black except a negative one, namely, as an absence of light of any kind. Hence, transferring our physics to our physiology, we consider that our sensation of white is a positive one, but that our idea of black arises simply from the absence of all sensation; or, to use a metaphor drawn from painting, black is our canvas, or background, on which all our sensation-pictures are drawn in white or colours; as a result of this, all our reasoning is confined to the pictures, while the background receives no attention.

The author, as one of the main points of his theory, strongly objects to this view. He denies that the natural unimpressed state of the visual sensation corresponds with black, appealing to every-day experience in support of the opinion. Any one who carefully examines his impressions after being for some time in a perfectly dark room, will observe a dark field, it is true; but if he tries, in imagination, to compare this with his sensation of a piece of the blackest velvet, he will be obliged to admit that the field is nothing approaching the latter in darkness; it is, in fact, only dark gray. Or as an easier and simpler test, let him compare the black after-image of a white disk with the general field given by his closed and darkened eyes, and he will observe a similar contrast.

The author's view is that the impression of black, like that of white, can only be derived from external sources; and that consequently black is a perfectly independent visual sensation, which should be studied physiologically like those of white, or red, or blue. On physiological grounds it is no more reasonable to consider black as the absence of white, than white as the absence of black, or blue as the absence of yellow, or to consider a sphere as the absence of solids of every other form.

On this principle he proceeds to discuss the sensation of gray. He objects to the usual mode of defining different shades of gray as merely different *intensities of light*. He considers any sensation of gray as a combination of the two independent sensations, black and white, in certain proportions; he calls this accordingly a *black-white* sensation, and he proposes to express it in a mathematical form. The full and perfect extreme sensations are practically unknown, and therefore no positive quantitative expressions can be used for them. But it is quite permissible to give an algebraical idea of the difference between intermediate gradations, and this may be done in the form of a ratio, or fraction, of which the two components express the assumed amounts of white and black respectively that are combined in the sensation. For example, there must be a practical gray (though we cannot identify its exact shade) which is intermediate between white and black, resulting from an equal force of each sensation. Here therefore if W = the force of the white sensation, and B = that of the black one, $\frac{W}{B} = \frac{1}{1}$ or $= 1$. For a lighter gray in which there is twice as much white as black, $\frac{W}{B} = \frac{2}{1} = 2$. And for a darker gray, in which there is twice as much black as white, $\frac{W}{B} = \frac{1}{2}$. On this principle the pure white sensation would be expressed by $\frac{W}{0} = \infty$, and the pure black sensation by $\frac{0}{B} = 0$.

It is possible, still retaining the principle, to give a more convenient expression for the brightness or lightness (*Helligkeit*) of any black-white sensation; thus, the degree of brightness may be expressed by the ratio which the *white element* bears to the *whole sensation*, or $= \frac{W}{W+B}$. Thus the brightness of the medium gray will be $= \frac{1}{1+1} = \frac{1}{2} = 0{\cdot}5$; and that of the mixture of two white to one black will be $= \frac{2}{2+1} = \frac{2}{3} = 0{\cdot}66$; and that of the mixture of two black to one white $= \frac{1}{1+2} = \frac{1}{3} = 0{\cdot}33$. The brightness of pure white will be $= \frac{1}{1+0} = 1$, and that of pure black $= \frac{0}{0+1} = 0$. This mode of definition corresponds to the usual practical idea of the *intensity* of white in gray, but it differs from it by acknowledging the independent black element in the composition.

In the fifth memoir we at length get a statement of the fundamental features of the author's theory, so far as the black-white sensation is concerned.

He begins by objecting to the treatment of white as a mixture of complementary colours, as blue and yellow, or red and green, or of all colours together, an idea which has arisen solely from physical considerations. No one, he says, can pretend that the least trace of any other colour can be distinguished in a pure white sensation; all that can be said is that the sensation of white is produced by a mixture of light of different wave-lengths. But the sensation is a perfectly independent one, like black, or red, and must be so considered in an investigation into the *rationale* of the visual perceptions.

Since the physiologist considers all sensations as called into existence by physical processes of the nervous system (for otherwise every physiological investigation would be objectless), he must assume so-called psycho-physical processes or movements which correspond to the sensations of black, of white, and of all shades between them. In what part of the nervous system these psycho-physical processes are situated it is impossible to say; suffice it that, somewhere in the nervous apparatus of the eye and the parts of the brain standing in functional relation therewith, a substance must be sought, with the changes or motion of which the sensation is bound up; this substance may be called the "visual substance" (*Sehsubstanz*).

The action of this substance may be studied in two ways: either *à priori*, by considering the physical influences brought to bear upon it, or, *à posteriori*, by considering the sensations resulting from its changes. The former mode has hitherto been of little profit, for

[1] Continued from p. 613.

although we can follow the ether vibrations to the retina, it has not been possible to trace what happens beyond. We can, indeed, compare the physical influences with the sensations produced, but we are obliged, in doing so, to skip over the intervening physiological steps where the chief interest lies. Hence the backward study of the processes, as inferred from their results, affords the best chance of success.

As to the general nature of the action of the visual substance, we have a choice between the idea of mechanical vibrations and that of chemical changes. Modern physiology points to the latter, for the general physiology of the nerves has sufficiently shown that all movement and all activity of the nervous substance produces chemical changes in it, and all our representations of changes of sensitiveness, fatigue, and restoration after activity, are founded on the assumption of such chemical changes. And however varied may be the views as to the details of this action, so far is certain that the continual presence of chemical processes in every vital and sensitive substance is a fact, and that material change is the most universal known property of every living thing.

It is therefore taken for granted that light produces chemical changes in the nervous apparatus of the visual organs; and what we term fatigue and change of sensitiveness depend, by general consent, on chemical changes of the sensitive substance. Hitherto, however, it has been customary only to consider this (so far as black and white are concerned) as an effect of *white* light; the element of black being neglected altogether, as already explained. The author proposes to correct this error, and he formulates his extended theory as follows:—

The two kinds of sensation which we call white (or light) and black (or aark) correspond to two distinct kinds of chemical action in the visual substance; and the various proportions in which these appear in the mixed sensation of gray, correspond to the same proportions of intensity of these two psycho-physical processes.

This is the simplest explanation conceivable, and it fulfils every condition demanded by general nervous physiology. We must assume a sensitive substance in the visual apparatus, which suffers a change by the action of light, and this change is generally believed to be a chemical one; and when the stimulating action is removed there must be a corresponding change in the other direction, giving a return to the normal condition. If the former change is assumed to be a partial consumption of matter, then the opposite change must be a restitution; if the former change is an analytical or disintegrating one, the latter must be a synthetical or reintegrating one, and so on.

Now the latter process, by which the living organic substance replaces the quantity lost by stimulation or activity, is usually called *assimilation*, and the author retains this name. The previous or contrary process, where the loss is caused by stimulation or activity, he calls *dissimilation*. Having to use these terms very often he denotes them by the letters A and D respectively.

These two processes result from the knowledge of physiology in general, and if they are correct, there is no reason why, as heretofore, only one of them, D, should be admitted to a theory of visual perception, and the other, A, excluded from it. The author's theory of the black-white sensation, therefore, embodies the proposition that *the sensation of white corresponds to dissimilation, and that of black to assimilation of the visual substance*, so that our visual sensations furnish a psychical expression of the correlation of the changes in the matter of this substance.

The following propositions are easily deducible from this principle.

The degree of lightness or darkness of a colourless visual sensation corresponds with the proportion between the intensities or magnitudes of the D and A actions respectively. For the medium gray these actions are equal, $\left(\frac{D}{A} = \frac{W}{B} = 1\right)$, so that the state of the visual substance remains constant. For a lighter gray D is greater than A, while for a darker gray the reverse is the case.

If we call all stimulating actions which favour dissimilation, D stimuli, and if we borrow from general physiology the proposition that the magnitude of the reaction with which an organ answers to its stimulus depends also on the mass of the excitable substance it offers to be acted on, we get the principle that the *magnitude of the dissimilation caused by a D-stimulus depends not only on the force of this stimulus, but also on the quantity of the excitable substance present.*

But the ability of an excitable substance to be set by a stimulus, in a state of excitation, is called its excitability (*Erregbarkeit*), and the previous proposition may be thus expressed:—

Every increase of the excitable substance necessitates a raising, every decrease a lowering, of the D-excitability of the visual organ. Hence the sensation of medium gray implies a uniformity, every brighter sensation a decrease, and every darker sensation an increase of the D-excitability. And it follows that if, at the same time, images of different brightness fall on two places of equal D-excitability, the place of the brighter sensation will have its excitability lowered, and *vice versa*.

The author further explains the law, that in any compound sensation, the prominence of any particular single one is expressed by the ratio which the magnitude or "weight" of that sensation bears to the sum of all the sensations present. For example, in a gray, the prominence of white $= \frac{W}{W + B}$. If the sensation of yellow is also present in an amount $= Y$, it will be $= \frac{W}{W + B + Y}$, and the prominence of yellow will be $= \frac{Y}{W + B + Y}$.

These being the chief features of the author's theory he goes on to show how it is applied to explain the various phenomena already mentioned, particularly those of subjective vision.

The first point necessary to be explained is what may be called the normal state of the visual organs, *i.e.*, the sensation experienced when the eyes have long been closed and darkened, as on awaking in a perfectly dark room. It has already been explained that this sensation, although dark, is far removed from what we know as black. It follows from the theory that in this state the D and the A actions should be in equilibrium, *i.e.*, about equally great or $\frac{D}{A} = 1$, according to which the sensation should correspond to the medium gray.

The author remarks on the fact that, comparing the actual sensation with the brightest sun-light on the one hand and the blackest known velvet on the other, it would seem to be far nearer the black than the white; but we have no reason to believe that the darkest sensation we can get at all approaches absolute blackness. He thinks it possible that if we could get rays as near the black end of the scale as sun-light is near the white end, we should find their effect as powerful. But such rays do not exist in nature, and in our ignorance of them we cannot define accurately what may or may not be the true medium gray.

Next is given an explanation of *Simultaneous Contrast*. The before-mentioned experiments have shown that when one part of the visual organ is stimulated by light, the effect is to darken the sensation in the parts around. The theory admits of the explanation of this in several ways; but the author prefers the following:—In a partial stimu-

lus by light a reaction is set up not only by the parts directly stimulated, but by the surrounding parts; the former through increased dissimilation, the latter through increased assimilation, which, however, is most powerful close to the lighted part, and diminishes fast with the distance from it.

This explains why, in a lighted room, the parts in shade appear black, much darker than our sensation with closed eyes, although the D-stimulus is equally active in both cases; and not only do the so-called dark parts really reflect some light, but a portion of dispersed light by objective irradiation enters the eye, which latter is strongest in the immediate neighbourhood of the bright object. But the increase of the assimilation prevents the perception of this light, and thus the ground is darkened, and the boundaries of the bright object are more sharply defined and brought out.

It is a result of this theory, that when two neighbouring parts of the retina are both stimulated by light at the same time, each reacts on the other by increased assimilation, the effect of which is to reduce the brightness of both. Hence, a small white surface is brighter than a large one of the same objective material. This may be easily seen by putting a large sheet of white paper, and a small strip of the same, both on a black ground. Or hold against the sky a large sheet of black paper, near the edge of which a small hole has been pierced; the point of light thus produced will be far more intense than that perceived round the edge of the paper. This is also the explanation of the great apparent brilliancy of the stars, the objective illumination of which is so very weak.

Explanation of *Simultaneous and Successive Light Induction*. Following up the process above described for simultaneous contrast, suppose the white object on the black ground to be further steadfastly observed for a longer time. The increase of assimilation in the parts immediately surrounding the white will cause an increase of the excitable substance, and will thus bring about an increase of excitability there. Hence the constantly working inner stimulus and the weak dispersed light of the black ground will acquire more dissimilating effect, while the assimilation gradually becomes weaker. Hence will follow an increase of apparent brightness on the parts previously darkened by contrast; this is *simultaneous light induction*. At the same time that the ground brightens in this way, the part of the visual organ impressed by the white surface suffers, by the prolonged dissimilation, a diminution of the excitable substance, whereby the excitability diminishes and the apparent brightness consequently diminishes also. If the contrast be made with only a slight difference in shade, and if the observation be carried on long enough, a phase will ultimately set in, in which by the gradual brightening of the ground and darkening of the whiter surface, they will both acquire the same appearance, and the distinction between them will disappear. This may be easily proved by experiment, but to prevent the confusing effect of the outlines, it is better shown by making, on white paper, dark patterns with shaded edges, when the effect will be soon apparent.

As the illumination of the light surface decreases it loses its power to favour the assimilation in the neighbouring dark parts, while the dissimilation under the influence of the inner D-stimulus not only goes on, but finds a greatly increased excitability to work upon; *i.e.*, according to the theory, the proportion $\frac{D}{A}\left(\frac{W}{S}\right)$ becomes greater, which means that the sensation increases in brightness. Hence, after sufficiently long steadfast observation, the bright-light space appears, and when the eyes are shut the sensation remains, as before described, giving *successive light induction*.

The explanation of *Successive Contrast* is given in four illustrations:—1. Observe fixedly a white stripe left between two large black surfaces; it will be seen that the original brightness gradually diminishes, and if the black surfaces be suddenly removed so as to leave an entirely white ground, the stripe will appear upon it as an after-image of a dark gray. This is, according to the theory, the result of the sudden bright illumination of the neighbouring parts; before this took place the dissimilation was powerful on the stripe, and (as before explained) excited an assimilation on the neighbouring black parts; this increased the D-excitability, and when the black surfaces were removed the white suddenly began to act with great power, setting up an assimilating action on the stripe where the excitability had been just before diminished, and so resulted the darkening effect on the latter.

2. Observe a small black stripe between two large sheets of white paper; it will at first appear very dark, but will gradually become lighter, and if the white sheets be suddenly removed, it will appear light on the black ground. This is the ordinary simultaneous and successive light induction already explained.

3. Lay a narrow white stripe on a black ground, observe it for a time, and then suddenly remove it; the place where it was will then appear blacker, and its neighbourhood lighter, than before. While observing the white stripe, the excitability upon it was diminished, and that around it increased, on the principles already explained: and on its removal the neighbouring parts were more impressed, and the place of the stripe less so, by the inner stimulus and the faint light of the general black ground.

4. Observe a black stripe on a white ground, and then suddenly remove it, leaving the whole field white. The place of the stripe will appear a brighter white surrounded by a darker space of a gray tinge. This is simply the converse of No. 3. The excitability was raised on the stripe and lowered around it; and when the whole field became active as a stimulus, the sensation was more powerful in the former place than the latter.

Lastly, the author devotes a chapter to the consideration of the *fatigue* of the visual organ. He says this may arise from two causes. When a light-stimulus is received, both a D-action and an A-action are set up, as previously explained: the D-action will naturally fatigue the organ by the dissimilation of the visual substance, but a similar result may follow also from the A-action if the assimilation goes on at a greater rate than fresh matter can be provided by the blood-supply. After looking at any very bright object, as the sun, and then covering the eyes, the after-image is not at first negative, but positive, and this bright impression may last for a long time, although, if the vision be thrown on white paper, the image will appear darker.

The explanation is as follows:—While looking at the bright object there is set up not only a strong dissimilation, but also a very considerable though less strong, assimilation. By the first the D-excitability will be greatly diminished, and by the latter the material in store will be quickly used up. Hence in the darkened eye, the sensation caused by the inner D-stimulus will be opposed only by a very weak A-action, so giving an after-impression of light, but of no great power. As the blood affords fresh matter, the equilibrium will be restored, and the appearance will die away.

In making the experiments hereinbefore mentioned on subjective vision, many different phases set in; these, though generally attributed to chance, are really due, in a large measure to the complicated influences of fatigue, caused as above described, and to their interference with the regular course of the light-induction and other processes hereinbefore described.

The author states, in conclusion, that he is far from believing that the theory he has developed is perfect, or incapable of correction, but he considers it comes nearer the truth than any other. WILLIAM POLE

(*To be continued.*)

NOTES

The following botanical appointments have been recently made by the Colonial Office, on the recommendation of the Director of the Royal Gardens, Kew:—H. Trimen, M.B. Lond., F.L.S., Senior Assistant in the Department of Botany, British Museum, to be Director of the Royal Botanic Garden, Ceylon, in the place of Dr. Thwaites, C.M.G., F.R.S., who retires on pension with the title of Honorary Government Botanist. D. Morris, B.A., Trin. Coll. Dubl., F.G.S., late Assistant-Director of the Royal Botanic Garden, Ceylon, to be Director of the Botanical Department, Jamaica. H. Marshall Ward, scholar of Christ's College, Cambridge, to be employed for two years as Cryptogamist in the investigation of the coffee-leaf disease in Ceylon. He will be subordinated to the Director of the Botanic Garden, and will have the use of the Assistant-Director's house. Mr. Morris and Mr. Ward were formerly students of the Science and Art Department.

Our readers will deeply sympathise with Sir John Lubbock under the heavy affliction with which he has been visited by the death of Lady Lubbock, which took place on the 20th instant. Her natural abilities were of no mean order, and the warm interest she took in all her husband's pursuits must have afforded him at once encouragement and aid in many of his undertakings. Her sympathies also extended to her husband's friends, and not a few of our readers will be able to call to mind the kind and hospitable reception which they have met with at her hands. Though for some years not in robust health, it was not, we believe, until within the last few weeks that any serious apprehension was entertained of the result of her illness. Lady Lubbock contributed a paper on the Shell-Mounds of Denmark to the volume of "Vacation Journals" for 1862-63; from time to time she was a contributor to Nature, and some few of her writings have appeared in a published form elsewhere; these, however, would afford but a poor criterion of all that she has directly and indirectly done towards the advancement of natural science.

It is with extreme regret that we record the death, after a long and painful illness, of Charles Henry Jeens, the well-known line engraver. Most of our readers are acquainted with the beautiful portraits of "Scientific Worthies" that appear from time to time in Nature, and many of them can doubtless testify from personal knowledge to the truth and accuracy of these portraits. Few artists ever possessed so fully as Mr. Jeens that esoteric faculty—which so many lack—for realising in an engraving the salient and best expression of a face and of making a portrait really characteristic and life-like. This faculty he held to the last, and increasing illness and pain only seemed to sharpen it. Apart from their value as excellent likenesses these portraits are of high artistic value. Mr. Jeens was noted for the firmness and delicacy of his work, and nowhere are these qualities better shown than in his small portraits. We are glad to say that before he died he had completed several fresh engravings for the series of "Scientific Worthies," which will be issued in due course and possess a mournful interest of their own. Mr. Jeens was only fifty-two years of age when he died.

Mr. C. P. Edison, nephew of the great American inventor, has just died at Paris at the early age of twenty-four. He was his uncle's principal assistant in the production of the loud-speaking telephone, and was sent over to London by him to exhibit that instrument before the Prince of Wales, the Royal Society, &c. He had of late been engaged in applying his uncle's system of quadruplex telegraphy between Paris and Brussels.

At the annual general meeting of the Cambridge Philosophical Society on Monday evening last, Prof. Alfred Newton, F.R.S., was elected President in the place of Prof. Liveing, who has served two years. The Vice-Presidents, in addition to the retiring President, are Prof. Stokes and Dr. Michael Foster. The Secretaries remain as before. New Members of the Council: Dr. Phear (Master of Emmanuel College), Prof. Hughes (Woodwardian Professor), and Mr. W. D. Niven, of Trinity College. Prof. Cayley and Mr. W. M. Hicks, of St. John's College, read papers, the latter on the Problem of Two Pulsating Spheres in a Fluid. Prof. Newton, in assuming the Presidency, said he felt bound to put aside all his feelings against holding this responsible position, in view of the wishes of the Council, and also considering that his election was to be regarded not only as a personal compliment, but as a tribute to those studies of which, by virtue of his position, he might be held to be representative. The next meeting of the Society is on November 10, and the junior secretary, Mr. Glaisher, is authorised to receive all communications relating to papers to be read before the Society.

The sixth meeting of Russian naturalists will be opened at St. Petersburg on January 1. The Committee is composed of professors of the St. Petersburg University, Beketoff, Petrushevsky, Ovsiannikoff, Tamintzin, Wagner, Menshutkov, and Snostrantseff. The meeting will last for ten days, and will have eight sections: Anatomy and Physiology; Zoology and Comparative Anatomy; Botany; Mineralogy, Geology, and Palæontology; Chemistry and Physics; Astronomy and Mathematics; Anthropology; and Scientific Medicine.

The last verification of the axes of the Gothard tunnel between Airolo and Göschenen was to be made this week. It is now confidently expected that the workmen from the two extremities of the tunnel will shake hands midway in the mountain before New Year's Day.

Prof. A. H. Sayce appeals to the public through the *Times* on behalf of a tour of exploration in Biblical lands, in which Mr. W. St. Chad Boscawen, the well-known Assyrian scholar, is at present engaged. Through the kindness of a few friends funds have been raised to carry him as far as Beyrout, whence he hopes to travel through Northern Syria and the Tigro-Euphrates Valley, visiting and examining on his way the sites of Carchemish and other Hittite cities, Nineveh, Calah, Assur (the ancient Assyrian capital), Balawat (from which Mr. Rassam obtained the bronze gates now in the British Museum), and Bagdad. Bagdad will be a centre for exploring Ur. The success of the expedition will, of course, largely depend on the funds at Mr. Boscawen's disposal, and Mr. Sayce hopes, therefore, that he will be assisted in his work by those interested in the archæology of the East. Subscription will be received by the treasurer of the fund, Mr. Edmond Beales, Osborn House, Bolton Gardens South, South Kensington.

On Saturday, October 25, the five academies constituting the Institute of France had a solemn meeting to award the biennial prize granted every two years by one of the academies. The turn this year being that of the Academy of Moral and Political Sciences, the prize was taken by M. Demolombe, dean of the Faculté de Droit of Caen, author of a voluminous work on legislation. The meeting was presided over by M. Daubrée, actual president of the Academy of Sciences, who delivered a very short inaugural address; but the learned geologist did not omit to make allusion to the unity of composition of the whole solar system as testified by the analysis of aërolites.

During the last few weeks the workmen engaged in making a road near Colberg, in Pomerania, found several indications that they were in the neighbourhood of an ancient burial place. The proprietor of the site, Herr von Kamecke, being solicitous for the preservation of any remains which might be found, had some excavations made under proper control. Twenty urns were

found; most of them had been shattered by the penetration of roots of trees and other causes, so that some of their contents only could be rescued. However, three large and two smaller urns were saved, quite uninjured, and two other large ones were taken up much shattered. The contents of the urns consisted chiefly of a sort of glass beads, rings, and needles of bronze and some small fragments of bronze wire. One iron needle and two iron rings were also found. All the things saved have been handed over to the Pomeranian Historical and Antiquarian Society.

SEVERAL German newspapers strongly deprecate the undignified tone which seems to have reigned amongst the participators in the recent celebration at Pompeii. It appears that the majority of the visitors treated the whole matter as an excellent joke, and behaved very much as they would have done at a fair or at some other Neapolitan *fête*. Many of the archæologists who had come long distances to be present at the celebration, left the dead city in disgust at the behaviour of the multitude, long before the proceedings were half over. One of the articles referred to expresses the hope that in the year 1979 the Neapolitans will have sufficiently improved in manners as well as gained in seriousness, to render a repetition of the disgraceful scene impossible.

THE London correspondent of the *Scotsman*, who is usually particularly well informed, states the Treasury has definitely decided not to ask Parliament for the cost of fitting up the new Natural History Museum at South Kensington and for the removal of the Natural History Department of the British Museum thereto till 1881. We are glad to be assured, however, that this statement should only be received as a rumour, and is not yet sufficiently authenticated. Let us trust that it will not be authenticated at all.

WE have received vol. iv. of the *Entomologische Nachrichten*, edited by Dr. F. Katter, Gymnasiallehrer am k. Pädogogium zu Putbus, Insel Rügen (Quedlinburg: Vieweg). We believe this magazine was started a few years ago as a monthly publication; but it is now issued fortnightly. It supplies a want that doubtless was long felt amongst German entomologists, affording a medium for constant intercommunication, and containing, moreover, many biological and other notes of much more than ephemeral value, notices of interesting excursions, discussions on the best means of preparing insects for scientific study, some good notices of new books, useful general bibliographic information, &c. We imagine most working entomologists in this country who can read German already see it, those who do not will find it to their advantage to possess it.

THE death is announced of Dr. Eugen Dühring, the well-known author of the "Kritische Geschichte der allgemeinen Principien der Mechanik" and "Privatdocent" in Berlin. He was born in 1833 in Berlin.

THE Committee appointed by the Royal Irish Academy to investigate the rocks of the districts of the Curlew Mountains and about Fintona, have discovered in the supposed "Old Red Sandstone" fossils of Silurian types.

THE thirteenth session of the Whitehaven Scientific Association was opened on the evening of Tuesday, October 21, when a *conversazione* was held in the Town Hall, which was largely attended by the members of the Association and their friends. The president for the year, Mr. A. Kitchin, F.C.S., delivered an address eulogistic of the labours of Dalton, with reference specially to the atomic theory. Crookes's tubes illustrating the properties of "radiant matter" were exhibited, and many objects of interest in science and art were also displayed in the room. The Association, which now numbers nearly 300 members, has been of considerable benefit in popularising science, mainly in the direction of series of lectures. It has formed the nucleus of a museum intended to represent local natural history, and has also established a library of scientific works. It is to be regretted that classes, in connection with the Association, have not hitherto been successful; further efforts in this direction are desirable in order that the work of the society may have the permanent value which systematic teaching alone can give.

A LOCAL anthropological exhibition is to be opened at Kazan by the local society of naturalists. We wish success to this young society, which displays a remarkable activity, and the publications of which contain many most valuable scientific papers.

IN consequence of the great efforts recently made for the improvement of the several Electrical specialties, a Chambre Syndicale of Electricity has been established in Paris. The number of subscribers is seventy-five, and the first meeting took place on October 27.

M. BROCA has presented to the Anthropological Society of Paris the head of Ataï, the principal mover of the great Kanaki rebellion in New Caledonia, and of a native enchanter who was killed in the same battle as the chief. These two heads had been cut off by a soldier, preserved in spirit and brought to Paris by him as a curiosity. They will be submitted to a thorough scientific examination.

FOR the first time perhaps in the history of electric lighting two rival magneto-electric machines are illuminating the same hall. The Lontin and Siemens generators and lights are exhibited at about 120 yards from each other in the large hall of the Palais de l'Industrie, at Paris. Each electrical machine is worked by steam, and consumes a certain amount of horse-power. The competition is too recent to offer yet any definite opinion on the respective merits of the apparatus confronting each other.

TELEGRAMS from Murcia state that the city and celebrated *Muerta* were inundated by an immense waterspout which was formed in the sea at a distance from the coast on the night of October 14–15. Salt water was discovered at a distance of 45 kilometres from the sea. Another great atmospherical commotion was experienced three days afterwards. A night snowstorm enveloped the whole of Austria and Switzerland, and in Vienna the thickness of the snowfall was several inches. It is the first time since 1852 that snow has fallen so early in Vienna, but not the earliest time on record, as in 1769 it fell on October 12.

A CEYLON paper states than an illustrated work on the Lepidoptera of the island is to be published at the expense of the Colonial Government.

RECENT intelligence from Victoria states that coal has been found on the Murray River near its confluence with the Murrumbidgee.

THE Phylloxera has appeared in the district of Geelong, Victoria.

A BRILLIANT meteor was observed at 5 P.M. on the 13th at Belluno, Italy. It was first bright red and then greenish white, and moved from east to west, at an angle of 45 deg. with the horizon.

THE Société française de Physique commences its meetings for the approaching session of 1879–80 on November 7.

WE would call attention to a very useful Index which has been begun in the *Gardeners' Chronicle* of October 11. It is intended to comprise references to the *more important* plants mentioned in the *Chronicle* from 1841 to 1878, including numerous original

descriptions by Lindley, Hooker, De Candolle, &c. This Index we think is likely to prove useful to botanists at large, and especially to those who are interested in the history of cultivated plants, and who may wish to know where to lay their hands on figures or descriptions of them.

THE applications of science at least seem to be obtaining some attention at the Antipodes; Stillwell and Co., of Melbourne, send us the following announcement of a new work to be published by them: "The Chemistry of Agriculture," by R. W. Emerson MacIvor, A.I.C., F.C.S., &c., lately Senior Demonstrator of Theoretical and Practical Chemistry, Anderson's University, Glasgow, with Appendices: Victorian Geology in its Relation to Agriculture, by Norman Taylor (of the late Geological Survey). The Conservation of Water for Agricultural and Pastoral Purposes, by G. Gordon, M.I.C.E. Suggestions on the Maintenance, Creation, and Enrichment of Forests, &c., by Baron von Mueller, K.C.M.G., F.R.S., &c.

THE Astro-physical Observatory on the Telegraphenberg, near Potsdam, was completed during September last, and has now been definitely handed over to its scientific directors.

PROF. SILVANUS THOMPSON has published a pamphlet of 74 pp. on apprenticeship schools in France, a subject on which he read a paper at the recent meeting of the British Association. The little book deserves the attention of all interested in technical education.

THE West London Scientific Association issue a very satisfactory Report for 1878–9.

THE museum of the St. Petersburg Academy of Sciences has made a valuable acquisition in the head of a *Rhinoceros tichorhinus*, very well preserved and covered with patches of hair. It is a part of a nearly complete carcass which was discovered on the banks of a tributary of the Yana, some 130 miles north of Verkhoyanak.

MESSRS. CASSELL have sent us the first two parts of a work on "European Ferns," illustrated by beautifully coloured plates. The text is by Mr. James Britten.

WE notice a useful publication undertaken by the Kieff Society of Naturalists, being a complete index of all works on mathematics, natural science, and medicine that have appeared in Russia during the years 1872 to 1877. The index for these five years has already appeared.

ANOTHER useful private undertaking is a weekly paper, *Rossiyskaya Bibliografia* (Russian and Slave Bibliography), appearing at St. Petersburg; it contains the titles of all Russian and Polish publications, with short notices about some of them.

MESSRS. GRIFFITH AND FARRAN will shortly publish a book entitled "On the Leads; or, What the Planets Saw." The object of the work is to bring the planets of our system into nearer acquaintance, making each give an account of itself to a little girl who watches them through her father's telescope on the leads of the house; their mythological character being made the mouthpiece of their astronomical and physical history. It is written and illustrated by Mrs. A. A. Strange Butson.

THE additions to the Zoological Society's Gardens during the past week include two Bonnet Monkeys (*Macacus radiatus*) from India, presented respectively by Mr. S. E. Phillips and Mr. J. E. Medley; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mrs. Franklin; a Lesser Black-backed Gull (*Larus fuscus*), British, presented by the Rev. F. H. Addams; a Mississippi Alligator (*Alligator mississippiensis*) from North America, presented by Capt. J. H. Mortimer; a Garnett's Galago (*Galago garnetti*) from East Africa, a Banded Ichneumon (*Herpestes fasciatus*) from West Africa, a Sœmmerring's Antelope (*Gazella sœmmerringi*) from Abyssinia, two Dufresne's Amazons (*Chrysotis dufresniana*) from South-East Brazil, purchased.

THE SANITARY CONGRESS

THIS Congress continued its meetings at Croydon during last week, when several interesting addresses were given. Mr. Douglas Galton, in his address last Thursday, spoke of that large class of conditions which are the direct result of the circumstances to which man is exposed in consequence of living in communities. All living beings are in a continual condition of change, which results in their throwing off from the body matters which poison earth, air, and water, unless space, time, and opportunity are afforded for the counteraction of these deleterious effects. He showed how thus resulted both epidemic and zymotic diseases, the presence or absence of which in any locality, and the degree of their virulence depend on the sanitary surroundings. Cholera and dysentery are principally connected with the condition of the water supply; while an epidemic prevails the question whether a given population shall suffer or escape may almost be predicted from a chemical analysis of the drinking water. It is to the physiologist and the chemist that we must look for the causes from which these baneful effects arise, and what are the conditions which should be altered to prevent or remove them. The engineer steps in after these causes have been pointed out, and it is for him to design the methods of prevention or removal.

In places where many dwellings are congregated together the requirements for health may be classed as—first, those that are common to the community, such as the supply of good water, the removal of foul water, and the removal of refuse matter; and secondly, those which immediately concern the individual householder, such as the condition of his house and the circumstances of its occupation. It is the interest of every person in a community that every other member of the community should live under conditions favourable to health. Each year, as the population increases and as dwellings multiply, so does the importance of promoting these conditions increase; and so long as preventible diseases exist throughout the country, we must not delude ourselves with the idea that we have done more than touch the borders of sanitary improvement. There are few subjects in which so many professions of progress have been made in the last few years as in the theoretical knowledge of how to provide a healthy dwelling and a healthy town. Books innumerable have been written upon the question. Physiologists have invented every conceivable theory; patentees have invented every conceivable description of apparatus; engineers, architects, and builders overwhelm you with professions of their knowledge of sanitary principles, and millions of money have been spent in furthering the schemes they have devised; and yet, in spite of all these efforts, there are few houses and very few towns where you would not easily detect some grievous sanitary blunders. Mr. Galton believes this to be due, in the first place, to the fact that the majority of men prefer anything to thinking for themselves. They like to obtain their knowledge as they do their hats—from a shop, ready-made. In the second place, the sanitary education of the country has not been brought into a system. In the third place, it has always seemed to Mr. Galton that the system under which the Government advances money for sanitary works, whilst of great *primâ facie* advantage in one point of view, yet has its disadvantageous aspect. Mr. Galton then entered into some detail as to the best system to be adopted for encouraging and carrying out sanitary works.

He thinks that we should have reached a higher level of sanitary improvement in this country than now prevails, if the Government had limited itself to its more legitimate functions, viz., first, the enactment of laws requiring sanitary defects to be removed; and second, the promotion of measures for diffusing a sound education in sanitary knowledge; instead of pursuing the course of endeavouring to dictate the exact measures to be followed in each case. But it may be asked, What is sanitary knowledge? It is frequently assumed that drainage and water-supply are the principal subjects which are embraced in the term; but these only make up a small part of the subject. At the present time there does not exist any treatise which brings to a focus the various problems of mechanical and physical science, upon which the knowledge is based.

Mr. Galton then gives several instances in connection with the construction of houses to illustrate the variety of the problems to be solved. A sanitarian tells us that health depends on pure air and pure water. If a site is to be selected, it requires a consideration of its position with respect to its surroundings. It requires a knowledge of the temperature of the air and of the soil; what are the

prevailing winds; what is the amount and incidence of the rainfall; and what is the percolative capacity of the soil. The engineer cannot interfere with the general conditions of a climate, but he may produce important changes in the immediate surroundings of a locality: he may modify the condition and temperature of the soil; he may control atmospheric damp; he may arrange for the rapid removal of rainfall, or he may cause the rainfall to be retained in the soil, to be given out gradually in springs, instead of passing away in torrents to flood the neighbouring districts.

Mr. Galton showed by comparing the death-rate in the model lodging-houses in London with that of other districts that any extraordinary degree of unhealthiness in towns is unnecessary.

One important step in knowledge of sanitary construction is to learn how to obtain pure air in a building. What is pure air? What are the impurities which make the air of a town so different from the fresh air of the country? The volume of sulphuric acid from coal thrown up by our fires into London air is enormous. A cubic yard of London air has been found to contain nineteen grains of sulphurous acid. The street dust and mud is full of ammonia from horse-dung. The gases from the sewers pour into the town air. Our civilisation compels us to live in houses, and to maintain a temperature different from that out of doors. What are the conditions as to change under which we exist out of doors? Mr. Galton then proceeded to show that it is all but impossible to maintain a supply of pure air indoors. Any ventilating arrangements are only makeshifts to assist in remedying the evils to which we are exposed from the necessity of obtaining an atmosphere in our houses different in temperature from that of the outer air. On the other hand, means might be adopted to obtain as pure air as we can. Suspended matters exist in much smaller quantities at an altitude; at 100 feet they are greatly diminished; at 300 feet the air is comparatively pure. In Paris the air for the Legislative Assembly is drawn down from a height of 180 feet, so as to be taken from a point above many of the impurities of the town atmosphere. That is a reasonable and sensible arrangement, and might be usefully adopted in public buildings in towns. In the Houses of Parliament the so-called fresh air is taken from courtyards on the street level, from which horse traffic is not excluded. The maintenance of the standard of purity, or rather impurity, in a building, depends on ventilating arrangements. Ventilation chiefly depends on the laws which govern the movement of air, its dilatation by heat or contraction by cold; or, if ventilation is effected by pumps and fans, then upon the laws of the motion of air in channels, the friction they entail, and similar questions; therefore all these are matters for careful study. But when we apply the study to practice, other considerations occur. It may be summed up that, whatever the cubic space, the air in a confined space occupied by living beings may be assumed to attain a permanent degree of purity, or rather impurity, theoretically dependent upon the rate at which emanations are given out by the breathing and other exhalations of the occupants, and upon the rate at which fresh air is admitted, and that, therefore, the same supply of air will equally well ventilate any space, but the larger the cubic space the longer it will be before the air in it attains its permanent condition of impurity. Moreover, the larger the cubic space, the more easily will the supply of fresh air be brought in without altering the temperature, and without causing injurious draughts. "A room warmed by an open fire," Mr. Galton maintains, "is pleasanter than a room warmed by hot-water pipes. A warm body radiates heat to a colder body near to it. The heat rays from a flame or from incandescent matter pass through the air without heating it; they warm the solid bodies upon which they impinge, and these warm the air. Where the source of heat in a room consists of hot-water pipes, or low-pressure steam pipes, the air is first warmed, and imparts its heat to the walls. The air is thus warmer than the walls. When a room is warmed by an open fire, on the other hand, the warming is effected by the radiant heat from the fire, which passes through the air without sensibly warming it; the radiant heat warms the walls and furniture, and these impart their heat to the air. Therefore the walls in this case are warmer than the air. Consequently, in two rooms, one warmed by an open fire, and the other by hot-water pipes, and with air at the same temperature in both rooms, the walls in the room heated by hot-water pipes would be some degrees colder than the air in the room, and therefore colder than the walls of a room heated by an open fire; and these colder walls would therefore abstract heat from the occupants by radiation more rapidly than would be the case in the room heated by an open fire. And to bring the walls in the room heated with hot-water pipes to the same temperature as the walls in the rooms heated by the open fire would require the air of the room to be heated to an amount beyond that necessary for comfort, and therefore to a greater amount than is desirable. Besides theoretical knowledge, it is of essential importance that the sanitary architect, builder, or engineer, should have also practical technical knowledge of the subject. He should know what constitutes a good material and good workmanship. It is not only the officers of the army of sanitary constructors who require knowledge and education, but the foremen and the labourers, each in his own degree."

Prof. Corfield's address was on Sanitary Fallacies. After an interesting historical *résumé*, he dealt with some fallacies of the present day. Against all sanitary improvements whatever we find one argument continually brought—that things have gone on in the same way for many years, and there is no reason why they should be changed, that our forefathers from generation to generation lived under unsanitary conditions, and why should we not do the same? that cholera, or enteric fever, or diphtheria has never broken out in a place, or in a particular house, and so it need not be expected! Dr. Corfield showed how fallacious and mischievous this argument is. The arguments brought forward to support the spontaneous origination of the poisons of typhus and enteric fevers, of diphtheria, and of cholera, are most of them fallacious in the extreme, and the arguments advanced to prove the *de novo* origination of the poison of enteric fever, are of themselves sufficient to render it in the highest degree improbable. They are, indeed, so weak, that no one really capable of judging the value of a scientific argument, could from them come to any other conclusion than that the position was untenable. But a practical and very serious mischief has arisen from the spread of these doctrines. In the majority of cases no pains are taken to destroy the excremental discharges of patients suffering from such diseases, a neglect apt to lead to very dangerous consequences.

"But," Dr. Corfield went on to say, "there is still a great fallacy abroad in connection with the question of the removal of refuse matters from the vicinity of habitations. People talk and write as if the water-carriage system and the Conservancy systems stood upon the same footing—the principal of the one being the *immediate* removal of excretal matters from houses, and that of all the others being, as their name indicates, the keeping of such matters in and about the house for a certain time. The one is a correct principle, the other is a false one, and it is no argument at all to say that where the water-carriage system is badly carried out, the result may be worse than where the Conservancy system is carefully managed. In sanitary matters, as well as in everything else, we should follow correct principles. If we do not, but by arguments equally specious and fallacious, try to persuade ourselves that 'practically speaking' (according to the cant phraseology of the day) better results may be obtained by following false principles, nothing is more certain than that by an inexorable law of nature true principles will assert their position, and we shall be punished for our mistake by being landed in difficulties greater than we had to contend with at the outset. It is a very old and often-exposed fallacy to argue against the use of a thing from the abuse of it, and to argue against the water-carriage system because when surface drains have been called upon to do the duty of sewers, for which they were not intended, and of which they are not capable, or because the sewage has been turned into the water-courses, which have thus become unfit to supply water for domestic purposes, is an excellent example of this kind of fallacy."

Dr. Corfield went on to show that water containing the least quantity of organic matter must be regarded as dangerous, and that absolutely pure water should be insisted on, as the only safe form for sanitary purposes. With regard to dietetics, Dr. Corfield referred to the fallacies which existed for some time, as to the dietetic value of gelatine. He could not but think that it was a mistake to utterly condemn alcoholic liquors.

"There are those—" he said, "and I think there always will be—who cannot believe that the exquisite *bouquet* of the wines of France, of Italy, and of Spain is only fit to be smelt, there may even be those who are wicked enough to insinuate that if people do not taste them they show a lamentable deficiency in the cultivation of an important sense. He referred in conclusion to the anti-vaccination fallacy, and showed that statistics are dead against it.

Under the title of "Geology in Relation to Sanitary Science," Mr. Alfred Haviland gave some valuable hints as to what would be the practical difficulty in realising any of the dreams of a

future proper state of society. He showed that even under the most favourable conditions of physique and surroundings population would so increase that migration would be an absolute necessity, the emigrants thus finding themselves in conditions totally different from those they left. They would stand face to face with the stern reality of change; a change so great they could not realize it. Help is called for; and science like a good genius, extends her hand. The dreamer and the dream are gone. Large as our world may be, it never has been, and we have no grounds for believing it ever will be, a universal paradise: and without it becomes so, the people of the dream can never become realities. We find not a single writing in the stones that records evidence of either uniform climate, uniform soil, or uniform conditions of any kind whatever conducing to the perfection of existence either among the lower or the higher classes of animals. The very factor so necessary to the perfection of type, viz., health, is the great factor of productiveness; and this productiveness is the factor of destruction by overcrowding. Over and over again has this been recorded on the rocks.

Man has not only spoiled many of the sites which his ancestors wisely selected as vantage grounds against the foe, the flood, and the drought; but is hourly spoiling his own form by his artificial habits, and laying at the same time the foundation for a still further departure from a natural standard in his offspring. He is polluting the soil on which his habitations stand, he is befouling his water-courses and springs, and he is poisoning the air he breathes. He has thus created surroundings from which he can with difficulty escape. "Now I hold," Mr. Haviland said, "that any institute established for the purpose of teaching us the science of living in a cleanly and wholesome manner—as regards water, air, and soil—should first of all teach in its schools what has already been taught by such men as I have mentioned, as a wholesome restraint against the pride which a little knowledge engenders. Before we can boast of any sanitary science, let us be able to point to our researches on the climates, the soils, the diseases we find at home and abroad in our vast colonies. Let the crust of the earth in various parts of the globe be thoroughly examined in its relation to diseases—recollecting that had not man been born, there are certain spots in this earth that produce certain specific poisons, the chemical constitution of which we know nothing. Such spots should be mapped, after having been thoroughly investigated as to soil and climate, for the use of emigrants, colonists, and those in command of our expensive but necessary soldiery."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—During Prof. Maxwell's illness, Mr. W. Garnett is lecturing for him at the Cavendish Laboratory, on Voltaic Electricity, Electro-magnetism, and Electric Measurements; the lectures are experimental. Mr. Garnett is also giving a more elementary experimental course of lectures on Mechanics and Hydrostatics, adapted to candidates for the First M.B. and First Part of the Natural Sciences Tripos. Prof. Stuart's workshop will be open for pupils this term at the New Museums. Practical instruction in the use of tools in wood or metal is provided, and further practical instruction for those who already have a sufficient knowledge of the use of the tools. During the present term his lectures will be on Mechanism. Mr. W. J. Lewis, M.A., Fellow of Oriel College, Oxford, has been incorporated as M.A. of Cambridge, and entered at Trinity College. Prof. W. H. Miller, F.R.S., Professor of Mineralogy, being in ill-health, Mr. W. J. Lewis has been appointed his deputy for twelve months, and Prof. Miller has assigned two-thirds of his whole annual stipend to his deputy. Mr. Lewis has for some time been working very assiduously in the Mineralogical Museum, and is now lecturing on Mineralogy, while in the Easter Term he intends to lecture on Crystallography and Crystallographic Physics. Next term Prof. Stuart's lectures will be on the Theory of Structures. Prof. Challis's lectures on Practical Astronomy are postponed on account of ill-health. Prof. Cayley will lecture this term on Differential Equations.

THE City and Guilds of London Institute for the Advancement of Technical Education, announce the opening of their technical classes, at Cowper Street School, Finsbury. In the section of applied physics, Mr. W. E. Ayrton will deliver a course of twelve lectures on "Some of the Practical Applications of Electricity and Magnetism," commencing on Monday, November 3, at 7 p.m. In that of applied chemistry, Dr. H. Armstrong, F.R.S., will deliver a similar course on "The First Principles of Chemistry," commencing Wednesday, November 5, at 8 p.m. An inaugural lecture will be delivered by Mr. Ayrton, on Saturday, November 1, at 8 p.m., on "The Improvement Science can Effect in our Trades, and in the Condition of our Workmen." A class in connection with this for the study of blowpipe analysis and assaying, will be commenced next week at the Birkbeck Institution, by Mr. G. Chaloner, F.C.S.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, October 20.—M. Daubrée in the chair.—The following papers were read:—Researches showing the power, the rapidity of action, and the varieties of certain inhibitory influences of the brain on itself or on the spinal cord, and of this latter centre on itself or on the brain, by M. Brown-Séquard.—Discovery of a small planet, by Mr. Peters (telegram from the Smithsonian Institution).—Observation of the planet 206, Peters, at the Paris Observatory, by MM. Henry.—Observations of declination, inclination, and horizontal intensity in the basin of the Mediterranean, by M. de Bernardière. These observations were made during a voyage of the training-ship, *La Flore*, in 1878-79. The numbers for some twenty-six places are tabulated.—On whole functions, by M. Picard.—On the Laurent saccharimeter, by M. Laurent. Two improved models were presented, giving more light and distinctness, while the reflections in the tubes are suppressed.—New researches on the mode of union of cells of the mucous bodies of Malpighi, by M. Ranvier. These cells, formed of masses of protoplasm with nuclei, are united by protoplasmic filaments, which are common to them and each of which does not result from junction of two filaments placed end to end, nor is the nodule occupying their middle the mark of a junction or juxtaposition; it is an elastic organ, which allows of easy enlargement of the spaces destined for circulation of nutritive juices between the cells.—On asphyxic glycæmia, by M. Dastre. Cl. Bernard affirmed that a prolonged asphyxic state destroyed the glycogen of the liver, and made the sugar disappear from the blood. Some physiologists hold, on the contrary, that in accordance with Lavoisier's theory, sugar accumulates in the blood when the oxygen (for its combustion) is diminished. M. Dastre considers we must distinguish between the effects of rapid asphyxia, immediately consequent on withdrawal of oxygen, and the consecutive effects of slow asphyxia (such as wasting of tissues and exhaustion of reserves). Rapid asphyxia may be realised in two ways, making an animal breathe air confined in a closed vessel, or making it breathe in rarefied air constantly renewed. He tried both on dogs, and found the quantity of sugar in the blood to vary in contrary direction to the quantity of oxygen (less oxygen, more sugar).

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE

"To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH

No. 496, Vol. 20] THURSDAY, MAY 1, 1879 [Price Sixpence

Registered as a Newspaper at the General Post Office.]

DIARY OF SOCIETIES.

London

THURSDAY, May 1.

Royal Society, at 8.30.—A Magnetic Survey of the Fortieth Parallel in North America between the Atlantic Ocean and the Great Salt Lake, Utah: Prof. Thorpe.—On Certain Definite Integrals occurring in Spherical Harmonic Analysis, and on the Expansion in Series of the Potentials of the Ellipsoid and the Ellipse: W. D. Niven.—On the Origin of the Parallel Roads of Lochaber, and their Bearing on other Phenomena of the Glacial Period: Prof. Prestwich.

Chemical Society, at 8.—On the Volumes of Liquids at their Boiling Points obtainable from Unit Volumes of Gases: Dr. W. Ramsay.—On a Method of Precipitating Manganese entirely as Dioxide, and its Application to the Volumetric Determination of Manganese: S. Pattinson.—On the Determination of Nitric Acid as Nitric Oxide by Means of its Action on Mercury: R. Warrington.

Royal Institution, at 2.—Annual Meeting.

Linnean Society, at 8.—Note on the Occurrence of a Restiaceous Plant in Cochin China: Dr. Maxwell Masters.—On the Structure of the Pouched Rats of the Genus *Heteromys*: Dr. J. Murie.—Nutrition in its Relation to the Fertilisation of Flowers: Thos. Meehan.

FRIDAY, May 2.

Royal Institution, at 9.—Action of Anæsthetics: Prof. McKendrick.
Society of Arts, at 8.—The Wild Silks of India: Thos Wardle.
Geologists' Association, at 8.—The Dinosauria: Prof. Seeley.

SATURDAY, May 3.

Royal Institution, at 3.—Architecture: H. H. Statham.

MONDAY, May 5.

Geologists' Association.—Excursion to Newbury.
Medical Society, at 8.30.
Victoria Institute, at 8.
Society of Arts, at 8.—Recent Advances in Telegraphy: W. H. Preece.
Royal Institution, at 5.—General Monthly Meeting.
Odontological Society.—Action of Nicotine on the Teeth.

TUESDAY, May 6.

Zoological Society, at 8.30.—On Additions to the Menagerie: The Secretary.—Description of a New Species of Woodpecker, from the Island of Tyzus Sima, near Japan: Rev. H. B. Tristram.—Descriptions of New Genera and Species of Asiatic Lepidoptera Heterocera: F. Moore, F.Z.S.

Statistical Society, at 7.45.—The Feasibility of Compulsory Education in Ireland: W. Neilson Hancock, LL.D.

Royal Institution, at 3.—Schumann: Ernest Pauer.

WEDNESDAY, May 7.

Society of Arts, at 8.—The Government Patent Bill: W. L. Wise.
Entomological Society, at 7.

THURSDAY, May 8.

Royal Society, at 8.30.—On the Sensitive State of Electrical Discharges through Rarefied Gases: W. Spottiswoode and J. F. Moulton.—On the Action of Solid Nuclei: C. Tomlinson.—On the Results of the Magnetical Observations made by the Officers of the Arctic Expedition, 1875–76: Staff-Commander E. W. Creake.—On the Relation between the Diurnal Range of Magnetic Declination and Horizontal Force as observed at the Royal Observatory, Greenwich, during the Years 1841 to 1877, and the Period of Solar Spot Frequency: W. Ellis.

Mathematical Society, at 8.—On the Complex whose Lines join Conjugate Points of Two Correlative Planes: Dr. Hirst, F.R.S.—Note on a Geometrical Theorem connected with the Function of an Imaginary Variable: Prof. Cayley, F.R.S.—Notes on some Definite Integrals: The Late Prof. Clifford, F.R.S.; and a Paper by E. J. Routh, F.R.S.

Society of Arts, at 8.—Alizarine and Allied Colouring Matters: W. H. Perkin.

Royal Institution, at 3.—Dissociation: Prof. Dewar.

FRIDAY, May 9.

Royal Institution, at 9.—Habits of Ants: Sir John Lubbock.

SATURDAY, May 10.

Physical Society, at 3.
Geologists' Association.—Excursion to Orpington and Knockholt.
Royal Institution, at 3.—Architecture: H. H. Statham.

Printed by R. CLAY, SONS, and TAYLOR, at 7 and 8, Bread Street Hill, Queen Victoria Street, in the City of London, and published by MACMILLAN AND CO., at the Office, 29 and 30, Bedford Street, Covent Garden.—THURSDAY, May 1, 1879.

NATURE

"To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH

No. 497, Vol. 20] THURSDAY, MAY 8, 1879 [PRICE SIXPENCE

Registered as a Newspaper at the General Post Office.]

WANTED, Clean Copies of NATURE, No. 472, for November 14, 1878. Address—Office of NATURE, 29, Bedford Street, Strand.

MICROSCOPIC OBJECTS

Of superlative perfection, illustrating Histology and every branch of Microscopy. Catalogue post free and gratis on application.

PARIS UNIVERSAL EXHIBITION, 1878.

Prize Medal awarded for Excellence, Variety, &c.

EDMUND WHEELER, 48N, Tollington Road, Holloway, London, N.

TUITION for the UNIVERSITIES, CIVIL

Service, and Army.—Pupils prepared for the above by a Tutor in South Kensington. Address—TUTOR, Lamley's Library, Thurloe Place, South Kensington.

LIBRARY OF HARVARD UNIVERSITY, CAMBRIDGE, MASS., U.S.A.

Packages for the General Library, or for any of the Departmental Libraries (Astronomical Observatory, Botanic Garden, Bussey Institution, Divinity School, Law School, Museum of Comparative Zoology, Scientific School), may be sent to the Agents, Messrs. TRÜBNER & Co., 57 and 59, Ludgate Hill, London.

JUSTIN WINSOR, Librarian.

MIDLAND UNION OF NATURAL HISTORY SOCIETIES.

SECOND ANNUAL MEETING at LEICESTER, May 20 and 21, 1879, under the direction of the Leicester Literary and Philosophical Society.

CONVERSAZIONE and EXHIBITION of OBJECTS of SCIENCE and ART, at the Town Museum, on Tuesday Evening, May 20. Tickets, 2*s.* 6*d.*

GEOLOGICAL and BOTANICAL EXCURSIONS to CHARNWOOD FOREST, on Wednesday, May 21st. Tickets, 7*s.* 6*d.*

Tickets and Programmes are now ready, and may be obtained from the Hon. Sec. to the Union,

Mr. W. J. HARRISON, Town Museum, Leicester.

BUNSEN BATTERY, 40 Cells, 7-inch Car-

bons, £8, or 4*s.* 6*d.* per Cell. Grove, Trays, 10-pint Cells, £4. Bichromate, 12 half-gallon in Case, £8. ELECTRIC LAMPS, best make, 3 and 5 Guineas. Coils, London made, 1-inch spark, 70*s.* Rotary Engines. &c. Powerful HOLTZ ELECTRICAL MACHINES, special bargains, £4 to £20; guaranteed satisfactory and reliable. Apparatus for Frictional Electricity at very lowest prices. Lists post free.—F. H. BROOK, 107, Lorrimore Road, London, S.E.

The LANCASTER POCKET CAMERA

for plates 4¼ × 3¼ inch, having three double dry-plate Slides, Umbrella Stand, best Lens with plate of Diaphragms, &c., &c., £5. Particulars free.

The LANCASTER CARTE PHOTOGRA-

PHIC APPARATUS, with Chemicals, &c., &c., complete, £3 5*s.* FIRST QUALITY ASTRONOMICAL TELESCOPES with Object Lenses, by WRAY, 2¼-inch, £5 0*s.*; 2½-inch, £7 10*s.*; 2¾-inch, £10; 3-inch, £12 10*s.*; 3¼-inch, £15 15*s.*; 4-inch, £25; 4½-inch, £40; 5-inch, £55, &c. Capital Student's Microscope, £3 3*s.* Collegian's First Quality Microscope, £5 5*s.* Illustrated Catalogue, 3 Stamps.

J. LANCASTER & SON, Opticians, Birmingham.

DUNHEVED COLLEGE (LIMITED), LAUNCESTON, CORNWALL.

Seven hours from London. SEPARATE BEDROOMS. Systematic Teaching in SCIENCE, FOREIGN LANGUAGES, and UNIVERSITY COURSES.

Calendar post free from

THE PRINCIPAL—BENJAMIN RALPH, LL.B. Dub.

ROYAL POLYTECHNIC.—CLASSES for

the preparation of Students for University Examinations, under the direction of EDWARD B. AVELING, D.Sc., F.L.S. London University Matriculation, 1st and 2nd B.Sc., Preliminary Scientific M.B., Botany, Physiology, Chemistry. All the work practical.

"HALL MARK" FOR THERMOMETERS.

The Kew Committee of the Royal Society hereby give Notice that after this date all Thermometers verified at the Kew Observatory will be marked, free of expense, with their monogram, "K.O.," interlaced, and a register number, in addition to the maker's number.

The Table of Errors will be furnished as usual.

By order,
G. M. WHIPPLE, Superintendent.

Kew Observatory, December 13, 1878.
Scale of Charges for Verification, &c., post free on application.

A GENTLEMAN who is going on a Dredg-

ing Cruise round the British Isles would be glad to meet another Naturalist who would be willing to accompany him during the whole or part of the voyage.—For further particulars apply to C. P. OGILVIE, F.L.S. Sizeville House, Leiston, Suffolk.

LIVING SPECIMENS FOR THE MICROSCOPE.

THOMAS BOLTON, MICROSCOPIST'S and NATURALIST'S STUDIO, 17, ANN STREET, BIRMINGHAM.

T. B. has last week posted to his subscribers a specimen of *Elver*, or Fry of Eel, with Illustration and Description. He has also distributed *Volvox globator*, Pandorina, *Closterium moniliferum* and *rostratum*, Nitella, Chara, Amœbæ, Cristatella, Plumatella, Fredericella, Paludicella, Stephanoceros, Melicerta, Hydatina, &c. He has also ready, Fish Spawn (probably Perch) and growing Zoospores of Algæ, with Illustrations.

Weekly announcements will be made in this place of organisms T. B. is supplying.

Price List of Specimens on application, with Stamped Addressed Envelope.

Specimen Tube, One Shilling, post-free,

Twenty-six Tubes in course of Six Months for Subscription of £1 1s.

Price List of Specimens on application, with stamped addressed envelope.

LABORATORY, 38, GRACECHURCH STREET, LONDON, E.C.

A. ANTHONY NESBIT, F.C.S., WATER ANALYST,

Performs every description of Water Analysis on moderate terms.

Properly cleansed bottles for the reception of samples sent to any part of the Kingdom.

SHELLS.—A Gentleman who has lately

arrived in this Country has a quantity of Shells to dispose of, consisting of about 3,500 Specimens.—For particulars apply to RICHARDSON & Co., 13, Pall Mall, S.W.

DODO'S BONES.—I have some, Pelvis and

Leg, verified by Owen, and will sell, Museum or Collector. Please make offer.—CHARLES FOX, Surgeon, Stoke Newington, N.

SHEPPEY FOSSILS.

W. H. SHRUBSOLE, SHEERNESS-ON-SEA, respectfully intimates that the appeal recently made by him has been so heartily responded to, that he cannot receive any more orders for "extra selected" specimens at present.

Orders for 10*s.* Collections of 100 "good" specimens can be executed without delay.

"NOTES ON THE GEOLOGY OF SHEPPEY" post free on application.

ELECTRICAL, SCIENTIFIC, & PHOTO-

GRAPHIC APPARATUS.—Electric Bells, Fire and Thief Alarms, and Automatic Switches. Induction Coils, Frictional Machines, Lamps, and Batteries. Microphones, Wires, Magnets, Carbons, and all Materials. Repairs and Alterations. New Illustrated Descriptive Catalogue, one Stamp. Cameras, Dry Plates, Sensitive Paper, and all Chemicals. Photo. List free.—DALE & CRAMPTON, Manufacturing Opticians, 4, Little Britain, London, E.C.

MINERALOGY AND GEOLOGY.

A New List of Collections of Fossils, Minerals, and Rocks now ready, including Special Collections to illustrate the various Text-books, in Cabinets. List of Sections of Rocks for the Microscope. Blowpipe Apparatus and Materials of all kinds in Cases or separately. New Patterns of Geological Hammers, with prices. List of New and Second-hand Books of

JAMES R. GREGORY,
MUSEUM OF GEOLOGY,
88, CHARLOTTE STREET, FITZROY SQUARE.

MINERALOGY AND GEOLOGY.

FINE AND INTERESTING GENICULATED CRYSTALS OF CASSITERITE, BRITTANY.
CUPRITES, NATIVE COPPERS, AND CHALCOTRICHITES, SERVIA.
MOLYBDATES OF LEAD, UTAH.
SILVER ORES FROM THE "EMMA" MINE.
CALCITES, CUMBERLAND. CERUSITES, UTAH.
TABLE OF HARDNESS, 2*s.* 6*d.*

PRIVATE LESSONS AND EVENING CLASSES.

SAMUEL HENSON,
277 (*Late* 113*a*), STRAND, LONDON, W.C.

GEOLOGY.—In the Preface to the Student's

ELEMENTS of GEOLOGY, by Sir Charles Lyell, price 9*s.*, he says: —"As it is impossible to enable the reader to recognise rocks and minerals at sight by aid of verbal descriptions or figures, he will do well to obtain a well arranged collection of specimens, such as may be procured from Mr. TENNANT (149, Strand), Teacher of Mineralogy at King's College, London." These Collections are supplied on the following terms, in plain Mahogany Cabinets:—

100 Specimens, in Cabinet, with 3 Trays	£2	2	0
200 Specimens, in Cabinet, with 5 Trays	5	5	0
300 Specimens, in Cabinet, with 9 Drawers	10	10	0
400 Specimens, in Cabinet, with 13 Drawers	21	0	0

More extensive Collections at 50 to 5,000 Guineas each.

DIAMONDS AND OTHER PRECIOUS

STONES. Scientific opinion given as to GENUINENESS, PURITY, and VALUE.—BRYCE WRIGHT, 90, Great Russell Street, London.

DIARY OF SOCIETIES.

London

THURSDAY, May 8.

Royal Society, at 8.30.—On the Sensitive State of Electrical Discharges through Rarefied Gases: W. Spottiswoode and J. F. Moulton.—On the Action of Solid Nuclei: C. Tomlinson.—On the Results of the Magnetical Observations made by the Officers of the Arctic Expedition, 1875–76: Staff-Commander E. W. Creake.—On the Relation between the Diurnal Range of Magnetic Declination and Horizontal Force as observed at the Royal Observatory, Greenwich, during the Years 1841 to 1877, and the Period of Solar Spot Frequency: W. Ellis.

Mathematical Society, at 8.—On the Complex whose Lines join Conjugate Points of Two Correlative Planes: Dr. Hirst, F.R.S.—Note on a Geometrical Theorem connected with the Function of an Imaginary Variable: Prof. Cayley, F.R.S.—Notes on some Definite Integrals: The Late Prof. Clifford, F.R.S.—A Method of Constructing by Pure Analysis Functions X, Y, &c., which Possess the Property that $\int X Y d\sigma = 0$, and such that any given Function can be expanded in the Form $\alpha X + \beta Y + \gamma Z + \ldots$: E. J. Routh, F.R.S.—The Numerical Calculation of a Class of Determinants and a Continued Fraction: J. D. H. Dickson.—The Nephroid, Heptagon, &c.: Dr. Freeth.

Society of Arts, at 8.—Alizarine and Allied Colouring Matters: W. H. Perkin.

Royal Institution, at 3.—Dissociation: Prof. Dewar.

FRIDAY, May 9.

Royal Institution, at 9.—Habits of Ants: Sir John Lubbock.

SATURDAY, May 10.

Physical Society, at 3.

Geologists' Association.—Excursion to Orpington and Knockholt.

Royal Institution, at 3.—Architecture: H. H. Statham.

MONDAY, May 12.

Royal Geographical Society, at 8.30.—On the Modification of the External Aspects of Organic Nature produced by Man's Interference: Prof. G. Rolleston.

Society of Arts, at 8.—Recent Advances in Telegraphy: W. H. Preece.

TUESDAY, May 13.

Anthropological Institute, at 8.—Ethnology, Mythology, and Philology of Races of Early Culture, Babylonians, Etruscans, Egyptians, Japanese, &c.: Hyde Clarke.—Notes on some Irish Affinities: A. L. Lewis.—History of the South-Western Barbarians. Translated from the Chinese: A. Wylie.—The Spread of the Slaves, Parts 2 and 3, Sections 1 and 2: H. H. Howorth.

Royal Institution, at 3.—German Literature: Prof. Hillebrand.

West London Scientific Association, at 8.

Horticultural Society, at 1.—Scientific Committee.

WEDNESDAY, May 14.

Royal Microscopical Society, at 8.—On the Occurrence of Recent Heteropora: A. Wm. Waters.—New Species and Varieties of Diatomaceæ from the Caspian Sea: A. Grunow.

Geological Society, at 8.—On the Pre-Cambrian Rocks of Caernarvonshire: Prof. T. McK. Hughes.—Notes on the Structure of the Palæozoic Districts of West Somerset: A. Champernowne and W. A. E. Ussher.—The Whin Sill of Teesdale as an Assimilator or the Surrounding Beds: C. T. Clough.—On the Augitic Rocks of the Canary Islands: Salvador Calderon. Communicated by the President.

Society of Arts, at 8.—The Automatic Hydraulic Brake: E. D. Barker.

THURSDAY, May 15.

Royal Society, at 8.30.

Royal Institution, at 3.—Dissociation: Prof. Dewar.

Society of Arts, at 8.—History of Alizarine, &c.: W. H. Perkin.

FRIDAY, May 16.

Royal Institution, at 9.—Etude optique de l'Elasticité: Prof. Cornu.

SATURDAY, May 17.

Royal Institution, at 3.—Architecture: H. H. Statham.

Geologists' Association.—Excursion to Watford.

Printed by R. CLAY, SONS, and TAYLOR, at 7 and 8, Bread Street Hill, Queen Victoria Street, in the City of London, and published by MACMILLAN AND CO., at the Office, 29 and 30, Bedford Street, Covent Garden.—THURSDAY, May 8, 1879.

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE

*"To the solid ground
Of Nature trusts the mind which builds for aye."*—WORDSWORTH

No. 498, Vol. 20] THURSDAY, MAY 15, 1879 [Price Sixpence

Registered as a Newspaper at the General Post Office.]

DIARY OF SOCIETIES.

LONDON

THURSDAY, MAY 15.

ROYAL SOCIETY, at 8.30.—Note on a Recent Communication by Messrs. Liveing and Dewar: J. N. Lockyer, F.R.S.—On an Induction-Current's Balance, and Experimental Researches made therewith: Prof. D. E. Hughes.—On the Capillary Phenomena of Jets: Lord Rayleigh, F.R.S.
SOCIETY OF ANTIQUARIES, at 8.30.—Occurrence and Origin of the Greek Fret, or Key Pattern, in Mexico and Peru: R. P. Greg.—Remarkable Finds of Bronze Celts in Italy: W. M. Wylie, M.A.
CHEMICAL SOCIETY, at 8.—On Nitrification, Part 2: R. Warington.—On Alkaloids of the Veratrums, Part 3: Dr. Wright and Mr. Luff.—On Alkaloids of the Veratrums, Part 4: Dr. Wright.—On Alkaloids of the Aconites and on Japanese Aconite Roots: Dr. Wright and Mr. Luff.—On the Action of Hydrochloric Acid on Manganese Dioxide: S. Pickering.—The Composition of Milk in Health and Disease: A. W. Blyth.—Notes on the Effect of Alcohol on the Chemistry of Digestion: W. H. Watson.
ROYAL INSTITUTION, at 3.—Dissociation: Prof. Dewar.
SOCIETY OF ARTS, at 8.—History of Alizarine, &c.: W. H. Perkin.
ZOOLOGICAL GARDENS, at 5.—The Pleasures of Zoology: Prof. J. R. Greene.

FRIDAY, MAY 16.

ROYAL INSTITUTION, at 9.—Etude optique de l'Elasticité: Prof. Cornu.

SATURDAY, MAY 17.

ROYAL INSTITUTION, at 3.—Architecture: H. H. Statham.
GEOLOGISTS' ASSOCIATION.—Excursion to Watford.

MONDAY, MAY 19.

SOCIETY OF ARTS, at 8.—Recent Advances in Telegraphy: W. H. Preece.
VICTORIA INSTITUTE, at 8.—Ethnology of the Pacific: Rev. S. J. Whitmee.
ROYAL INSTITUTION, at 3.—The Intellectual Movement in Germany: Prof. Hillebrand.

TUESDAY, MAY 20.

ZOOLOGICAL SOCIETY, at 8.30.—Description of a Portion of a Mandible and Teeth of a Large Extinct Kangaroo (*Palæorchestes crassus*) from Ancient Fluviatile Drift, Queensland: Prof. Owen, C.B.—Descriptions of New Species of Halticidæ: Martin Jacoby.—On a Fourth Collection of Birds made by the Rev. G. Brown, C.M.Z.S., on Duke of York Island and in its Vicinity: P. L. Sclater.
ROYAL INSTITUTION, at 3.—Suggestions to Students and Readers of History: T. R. Seeley.
STATISTICAL SOCIETY, at 7.45.—On some Effects of a Crisis on the Banking Interest: John B. Martin, M.A.

WEDNESDAY, MAY 21.

METEOROLOGICAL SOCIETY, at 7.—On Observations of the Velocities of the Wind and on Anemometers: G. A. Hagemann.—On the Relation between the Height of the Barometer and the Amount of Cloud, as Observed at the Kew Observatory: G. M. Whipple, F.R.A.S.
ROYAL SOCIETY OF LITERATURE, at 8.—The Authorship of Shakespear's Plays: Sir Patrick Colquhoun, Q.C.
CROYDON MICROSCOPICAL SOCIETY, at 8.30.
SOCIETY OF ARTS, at 8.—Edison's New Telephone: C. W. Cooke.

THURSDAY, MAY 22.

ZOOLOGICAL SOCIETY, at 5.—Tails: Prof. Mivart.
ROYAL INSTITUTION, at 3.—Dissociation: Prof. Dewar.
SOCIETY OF ARTS, at 8.—Alizarine: Prof. Perkin.

FRIDAY, MAY 23.

ROYAL INSTITUTION, at 9.—Multiple Telegraphy: W. H. Preece.
QUEKETT MICROSCOPICAL CLUB, at 8.—On some Improvements in Microscopical Turn-Tables: C. Spencer Rolfe.—On Stained Sections of Animal Tissues and how to Prepare them: J. W. Groves.
SOCIETY OF ARTS, at 8.—The Harbour of Kurachee: W. J. Price.

Printed by R. CLAY, SONS, and TAYLOR, at 7 and 8, Bread Street Hill, Queen Victoria Street, in the City of London, and published by MACMILLAN AND CO., at the Office, 29 and 30, Bedford Street, Covent Garden.—THURSDAY, May 15, 1879.

W. F. STANLEY,

Mathematical Instrument Manufacturer

To H.M.'s Government, Council of India, Science and Art Department, Admiralty, &c.

Mathematical, Drawing, and Surveying Instruments of every description, of the highest quality and finish, at the most moderate prices.

Price List post free. *Engine Divider to the Trade.*

ADDRESS—
GREAT TURNSTILE, HOLBORN, LONDON, W.C.

NOW READY,
SECOND EDITION,

GRIFFIN'S CHEMICAL HANDICRAFT.

PRICE 4*s.* 7*d.* POST FREE.

A CATALOGUE OF CHEMICAL APPARATUS:

ILLUSTRATED, CLASSIFIED, DESCRIPTIVE.

Demy 8vo, 480 pp., Illustrated with 1,600 Woodcuts.

Most Complete and Cheapest List of Apparatus.

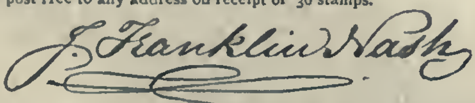
JOHN J. GRIFFIN AND SONS, 22, GARRICK STREET, LONDON, W.C.

ENGRAVINGS AND ELECTROTYPES

FOR SALE, at prices ranging from 1*s.* to 10*s.*, in good condition, ready for printing. Small, medium size, and large engravings, comprising a great variety of subjects, suitable for Publishers, Advertisers, and Amateurs. Specimen of any subject required sent post free on application.

FACSIMILE OF SIGNATURE for 3*s.* An exact copy of any name guaranteed. These signatures being engraved in bold relief, are useful for Stamping Books, Circulars, and Documents, or Marking Linen, and made type-high for ordinary Letterpress Printing.

Sent post free to any address on receipt of 36 stamps.



75, FLEET STREET, LONDON, E.C.

ARTISTIC.—To Ladies and Gentlemen with some leisure time, desiring to supplement their incomes, an opportunity is offered of acquiring the ART of DRAWING and ENGRAVING on WOOD in a thoroughly satisfactory and perfect style. The terms are moderate, and the hours can be made to suit the convenience of pupils. Persons residing in the country can receive full instruction by correspondence. For further particulars call or address Mr. J. FRANKLIN NASN, Artist and Engraver, 75, Fleet Street, London, E.C.

THE MINIATURE MICROSCOPE LAMP

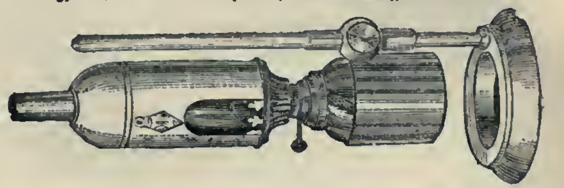
(REGISTERED)

PRICE 14*s.* PORTABLE TIN CASE FOR DITTO, 2*s.* 6*d.*

JAMES HOW & Co.,

SCIENTIFIC INSTRUMENT MAKERS,

5, *ST. BRIDE ST.* (*late* 2, *Foster Lane*), *LONDON.*



EDWARD PATERSON,

Electrical Engineer and Scientific Apparatus Manufacturer,

3, BEDFORD COURT, COVENT GARDEN, LONDON.

STEAM WORKS, GRAY'S INN ROAD.

Experiments in Electric Lighting carried out.

Electrical Apparatus of all descriptions for Lecture Purposes Loaned out.

APPARATUS FOR CLASS DEMONSTRATION and for SCIENCE SCHOOLS.
ELECTRIC LIGHT APPARATUS.
SIEMEN'S and GRAMME'S DYNAMO MACHINES and LAMPS for Hire and Purchase.
LARGE ASSORTMENT of RUHMKORFF COILS and VACUUM TUBES.
PROFESSOR HUGHES' MICROPHONE.
ELECTRIC BELLS and INDICATORS.
TELEPHONES and TELEPHONE CALL BELLS, WIRE, &c., for Fixing.
PROF. S. P. THOMPSON'S LANTERN SLIDE GALVANOMETER, 20*s.*
EDISON'S ELECTRIC PEN £8 8s.
ELECTRIC and MAGNETIC APPARATUS of all Descriptions.

New Illustrated Catalogue of 60 *pages post free* 6 *stamps.*

Orders over £2 carriage paid to any part of the United Kingdom.

RUDOLPH KOENIG,

(DR. PHIL.)

MANUFACTURER OF

ACOUSTICAL INSTRUMENTS.

TO ILLUSTRATE THE LAWS
AND TO PRODUCE THE PHENOMENA OF SOUND.

PARIS, 26, RUE DE PONTOISE.

CHEMICAL SOCIETY, at 8.—On Gardenin: Dr. Stenhouse and Mr. Groves.—On the Action of Sulphuric Acid on the Hydrocarbons of the Formula $C_{10}H_{16}$: Drs. Armstrong and Gilden.—Researches on the Terpenes, Camphor, and Allied Compounds, Parts 1 and 2: Dr. Armstrong.—Contributions to the History of Starch and its Transformations: H. T. Brown.—On the Boiling Points of Certain Metals and Metallic Salts: Dr. Carnelly and W. C. Williams.—On the Determination of Nitric Acid by Means of Indigo: R. Warington.—On Dry Copper-Zinc Couples and Analogous Agents: Dr. Gladstone and Mr. Tribe.—Notes on the Purple of the Ancients: R. Schunck.

LINNEAN SOCIETY, at 8.—Carpesium as Indigenous to Australia: F. M. Bailey.—Flora of Northern China: J. G. Baker and S. Le Marchant Moore.—New Polyzoa: Prof. G. Busk.—Australian Lichens in R. Brown's Herbarium: Rev. J. M. Crombie.

Printed by R. CLAY, SONS, and TAYLOR, at 7 and 8, Bread Street Hill, Queen Victoria Street, in the City of London, and published by MACMILLAN AND CO., at the Office, 29 and 30, Bedford Street, Covent Garden.—THURSDAY, June 12, 1879.

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE

"*To the solid ground*
Of Nature trusts the mind which builds for aye."—WORDSWORTH

No. 503, Vol. 20] THURSDAY, JUNE 19, 1879 [Price Sixpence

Registered as a Newspaper at the General Post Office.]

DIARY OF SOCIETIES.

LONDON

THURSDAY, JUNE 19.

ROYAL SOCIETY, at 8.30.—On the Existence of Liebreich's Protagon in the Brain: A. Gamgee and E. Blankenhorn.—The Measurement of the Ratio of Lateral Contraction to Longitudinal Extension of a Body under Strain: A. Mallock.—The Determination of the Effects of Tidal Friction by a Graphical Method: G. H. Darwin.—An Account of Experiments on the Influence of Colloids upon Crystalline Form, and on Movements observed in Mixtures of Colloids with Crystalloids; and other Papers: Dr. W. M. Ord.

CHEMICAL SOCIETY, at 8.—On Gardenin: Dr. Stenhouse and Mr. Groves.—On the Action of Sulphuric Acid on the Hydrocarbons of the Formula $C_{10}H_{16}$: Drs. Armstrong and Gilden.—Researches on the Terpenes, Camphor, and Allied Compounds, Parts 1 and 2: Dr. Armstrong.—Contributions to the History of Starch and its Transformations: H. T. Brown.—On the Boiling Points of Certain Metals and Metallic Salts: Dr. Carnelly and W. C. Williams.—On the Determination of Nitric Acid by Means of Indigo: R. Warington.—On Dry Copper-Zinc Couples and Analogous Agents: Dr. Gladstone and Mr. Tribe.—Notes on the Purple of the Ancients: R. Schunck.

LINNEAN SOCIETY, at 8.—Carpesium as Indigenous to Australia: F. M. Bailey.—Flora of Northern China: J. G. Baker and S. Le Marchant Moore.—New Polyzoa: Prof. G. Busk.—Australian Lichens in R. Brown's Herbarium: Rev. J. M. Crombie.

MONDAY, JUNE 23.

GEOGRAPHICAL SOCIETY, at 8.30.—Reports received from Mr. Keith Johnston, Commanding the East African Expedition:—(1) Excursion to the Usambara Hills; (2) Information obtained regarding Routes between Dar-es-Salaam and Lake Nyassa.

TUESDAY, JUNE 24.

ANTHROPOLOGICAL INSTITUTE, at 8.—On the Osteology of the Natives of the Andaman Islands: Prof. W. H. Flower, LL.D., F.R.S.—On Palæolithic Implements from the Valley of the Brent: Worthington G. Smith, F.L.S.—"Kemp How" Cowlam: J. R. Mortimer.—Portstewart and other Flint Factories of the North of Ireland: W. J. Knowles.—On some Eskimos Bone Implements from the East Coast of Greenland: W. J. Sollas, M.A., F.G.S.

METROPOLITAN SCIENTIFIC ASSOCIATION, at 7.—Annual Meeting.

WEST LONDON SCIENTIFIC ASSOCIATION, at 8.

HORTICULTURAL SOCIETY, at 1.—Scientific Committee.

WEDNESDAY, JUNE 25.

GEOLOGICAL SOCIETY, at 8.—The Formation of Rock-Basins: J. D. Kendall, C.E.—On *Lepidodiscus Lebouri*, a New Species of *Agelacrinites*, from the Carboniferous Series of Northumberland: W. Percy Sladen.—On Evidence that Certain Species of *Ichthyosaurus* were Viviparous: Prof. H. G. Seeley, F.L.S.—On *Dolichocephalus Prestwichi*, Seeley, an Ornithosaurian from the Stonesfield Slate of Kineton: Prof. H. G. Seeley.—On the Physical Geography of the North-East of England in Permian and Triassic Times: E. Wilson.—On the Diorites of the Warwickshire Coal-Field: S. Allport.—A Contribution to South-American Geology: George Attwood.—On the so-called Midford Sands: J. Buckman.—On the Ancient River-Deposit of the Amazon: C. B. Brown, Assoc. R.S.M.—The Glacial Deposits of Cromer: Clement Reid.—Notes on a Disturbance of the Chalk at Trowse, near Norwich.—The Submerged Forest of Barnstaple Bay: T. M. Hall.—On a Section of Boulder Clay and Gravels at Balleygalley Head, and an Inquiry as to the Proper Classification of the Irish Drift: T. Mellard Reade.—On the Augitic Rocks of the Canary Islands: Salvador Calderon. Communicated by the President.—On the Cambrian (Sedgw.) and Silurian Beds of the Dee Valley, as compared with those of the Lake-District: J. E. Marr.—On some Superficial Deposits in the Neighbourhood of Evesham: Rev. A. H. W. Ingram.

ROYAL SOCIETY OF LITERATURE, at 8.—On the Paris Literary Congress of 1878, and the International Literary Association: C. H. E. Carmichael.

FRIDAY, JUNE 27.

QUEKETT MICROSCOPICAL CLUB, at 8.

SATURDAY, JUNE 28.

PHYSICAL SOCIETY, at 3.

GEOLOGISTS' ASSOCIATION.—Excursion to Tunbridge and Tunbridge Wells.

CHEMICAL & PHYSICAL APPARATUS

BOTTLES, PURE CHEMICALS,

And every requirement for Science Classes, Private Study, or Business Purposes.

FLETCHER'S NEW FURNACE.

A perfect furnace for all purposes: can be used anywhere, with or without gas. Simple, cheap, not liable to damage, and always ready for instant use. Will fuse 6 lbs. metallic nickel to pour clean. The power is under the most delicate control, and delicate enamels can be fused in the open flame without protection. It is perfectly adapted for the most precise chemical operations, small forgings, steel and iron castings, &c., and has been carried about fields for heating rivets for fencing.

Illustrated List on Application.

EDMUND WHEELER, 48N, Tollington Road, Holloway, London, N.

ROYAL COLLEGE OF SCIENCE FOR IRELAND,

STEPHEN'S GREEN, DUBLIN.

SCIENTIFIC AND TECHNICAL EDUCATION.

SESSION 1879-80.

This College supplies a complete Course of Instruction in Science, applicable to the Industrial Arts, especially those which may be classed broadly under the heads of CHEMICAL MANUFACTURES, MINING, and ENGINEERING.

A Diploma of Associate of the College is granted at the end of the Three Years' Course.

There are Four Royal Scholarships of the value of £50 each yearly, with free education, including Laboratory Instruction, tenable for two years. Two become vacant each year. They are given to Students who have been a year in the College.

The Fees are £2 for each Course, or £10 for all the Courses of each year, with the exception of Laboratory Practice.

CHEMISTRY (THEORETICAL AND PRACTICAL), METALLURGY, &c.—Prof. HARTLEY, F.C.S.

MATHEMATICS, MECHANICS, AND MECHANISM.—Prof. HENNESSY, F.R.S.

DESCRIPTIVE GEOMETRY, DRAWING, ENGINEERING, AND SURVEYING.—Prof. PIGOT, C.E., M.R.I.A.

EXPERIMENTAL PHYSICS (THEORETICAL AND PRACTICAL).—Prof. BARRETT, F.R.S.E., F.C.S.

MINING AND MINERALOGY.—Prof. O'REILLY, C.E., M.R.I.A.

BOTANY.—Prof. M'NAB, M.D., F.L.S.

ZOOLOGY.—Prof. BRIDGE, B.A.

GEOLOGY.—Prof. HULL, M.A., F.R.S.

PALÆONTOLOGY.—Mr. BAILY, F.G.S.

The Chemical and Physical Laboratories and Drawing School are open daily for Practical Instruction.

Fee for Chemical Laboratory, £2 per Month, or £12 for Session. Fee for Physical Laboratory, £1 per Month, or £6 for Session. Fee for Drawing School, £3 for Session.

The SESSION commences on MONDAY, October 6th.

Programmes may be obtained on application at the College, or by letter or post-card, addressed to the Secretary, Royal College of Science, Stephen's Green, Dublin.

FREDERICK J. SIDNEY, LL.D., Secretary.

QUEEN'S COLLEGES, IRELAND.

PROFESSORSHIP of MEDICINE, QUEEN'S COLLEGE, GALWAY.

The Professorship of the Practice of Medicine in the Queen's College, Galway, being now vacant, candidates for that office are requested to forward their testimonials to the Under-Secretary, Dublin Castle, on or before the 29th instant, in order that the same may be submitted to his Grace the Lord Lieutenant.

The candidate who may be selected for the above Professorship will have to enter upon his duties on the 1st November.

Dublin Castle, 5th September, 1879.

UNIVERSITY COLLEGE, LONDON.

CHEMICAL TECHNOLOGY: Professor CHARLES GRAHAM, D.Sc.

Courses of Lectures on Applied Chemistry:—(1) Heating and Lighting, commencing October 7th; (2) Dyeing and Calico Printing, commencing October 10th. During the second term Courses on Chemistry of Brewing and Metallurgy.

Fees each Course, £2 2*s*. Four Courses, £5 5*s*. Chemical Laboratories open daily.

Prospectuses may be obtained from the College, Gower Street, W.C.

TALFOURD ELY, M.A., Secretary.

UNIVERSITY COLLEGE, BRISTOL.

The next SESSION will begin on OCTOBER 8th, 1879. The College supplies for persons of either sex above the ordinary school age, the means of continuing their Studies in Science, Languages, History, and Literature, and particularly in those branches of Applied Science which are employed in the Arts and Manufactures. The CHEMICAL LABORATORY is open daily from ten to five. Arrangements have been made, in connection with the DEPARTMENT of ENGINEERING and SURVEYING, by which Students may spend the six summer months as pupils with various Engineering Firms in and near Bristol. Information with regard to the lodging of Students will be given by the Principal, on application through the Secretary. Several SCHOLARSHIPS will be competed for early in October.

For prospectus and further information apply to

EDWARD STOCK, M.R.C.S., Secretary.

CHEMISTRY CLASSES.

Private Classes (Chemistry, Practical and Theoretical) for Matriculation, Preliminary Scientific First B.Sc. will commence in October. For further particulars apply to THOMAS ELLOFT, F.C.S., F.I.C., 55, Torriano Avenue, Camden Road, N.W.

LIVING SPECIMENS FOR THE MICROSCOPE.

THOMAS BOLTON, MICROSCOPIST'S and NATURALIST'S STUDIO, 17, ANN STREET, BIRMINGHAM.

T. B. has last week posted to his subscribers specimens of the beautiful clustered rotifer, *Lacinularia socialis*, with illustration. He has also sent out *Brachionus urceolaris, Stephanoceros Eichornii, Plumatella repens, Cristatella mucedo, Sida crystallina, Volvox globator*, &c.

Weekly announcements will be made in this place of organisms T. B. is supplying.

Specimen Tube, One Shilling, post-free,

Twenty-six Tubes in course of Six Months for Subscription of £1 1s.

Price List of Specimens on application, with stamped addressed envelope.

PORTFOLIO OF DRAWINGS, ONE SHILLING.

ROYAL SCHOOL OF MINES.

DEPARTMENT OF SCIENCE AND ART.

During the Twenty-ninth Session, 1879-80, which will commence on the 1st of October, the following COURSES of LECTURES and PRACTICAL DEMONSTRATIONS will be given:—

1. Chemistry. By E. Frankland, Ph.D., F.R.S.
2. Metallurgy. By John Percy, M.D., F.R.S.
3. Biology. By T. H. Huxley, LL.D., F.R.S.
4. Mineralogy. } By Warington W. Smyth, M.A., F.R.S., Chairman.
5. Mining. }
6. Geology. By John W. Judd, F.R.S.
7. Applied Mechanics. By T. M. Goodeve, M.A.
8. Physics. By Frederick Guthrie, Ph.D., F.R.S.
9. Mechanical Drawing. By Rev. J. H. Edgar, M.A.

The Lecture Fees for Students desirous of becoming Associates are £30 in one sum, on entrance, or two annual payments of £20, exclusive of the Laboratories.

Tickets to separate Courses of Lectures are issued at £3 and £4 each.

Officers in the Queen's Service, Her Majesty's Consuls, Acting Mining Agents and Managers, may obtain Tickets at reduced prices.

Science Teachers are also admitted to the Lectures at reduced fees.

For Particulars (free) or for Official Prospectus (price 6*d*., by post 7*d*.) apply to the Registrar, Royal School of Mines, Jermyn Street, London, S.W.

F. W. RUDLER, Registrar.

The POST of SENIOR MASTER in PHYSICAL SCIENCE

at Clifton College, Bristol, is VACANT, owing to Dr. MACGREGOR'S acceptance of a Professorship.—Apply to the HEAD-MASTER, giving particulars and references.

EVENING SCIENCE LECTURES.—Mr.

W. J. WILSON, F.C.S., M.S.T.E. (Demonstrator of Practical Physics at South Kensington), will commence a Course of about Sixty Lectures on Electricity, Magnetism, Light, Heat, and Sound, in the Theatre of the Birkbeck Institution, Southampton Buildings, W.C., on FRIDAY, October 10th, at 8 o'clock; to be continued on succeeding Fridays, at the same hour, and terminating with the Government Examinations in May. Fee for the Course, 7*s*. 6*d*. For detailed syllabus, particulars of special prizes, &c., apply to the Librarian.

GEORGE HENRY LEWES STUDENTSHIP.

This Studentship has been founded, in memory of Mr. George Henry Lewes, for the purpose of enabling the holder for the time being, to devote himself wholly to the prosecution of original research in physiology. The Studentship, the value of which is slightly under 200*l*. per annum paid quarterly in advance, is tenable for three years, during which time the student is required to carry on, under the guidance of a Director, physiological investigations to the complete exclusion of all other professional occupations. No person will be elected as a "George Henry Lewes Student" who does not satisfy the Trustees and Director first as to the promise of success in physiological inquiry, and second as to the need of pecuniary assistance. Otherwise all persons of both sexes are eligible. Applications, together with such information concerning ability and circumstances, as the Candidate may think proper, should be sent to the present Director, Dr. Michael Foster, New Museums, Cambridge, not later than October 15, 1879. The appointment will be made and duly advertised as soon as possible after that date.

THE MIDDLESEX HOSPITAL.

The WINTER SESSION will open on WEDNESDAY, October 1st, with an Introductory Address at 3 P.M. by Dr. SIDNEY COUPLAND.

The Medical School attached to the Hospital provides the most complete means for the education of Students preparing for the University of London, the Colleges of Physicians and Surgeons, and the Society of Apothecaries.

Two Entrance Scholarships of the annual value of £25 and £20, tenable for two years, will be competed for on September 29th and following days.

Further information may be obtained from the Dean or the Resident Medical Officer at the Hospital.

ANDREW CLARK, Dean.

EQUATORIAL TELESCOPE for SALE,

very cheap.—3⅜ object-glass, several eye-pieces, finder, rackwork stand, unusually strong, perfect condition.—Address ASTRA, care of the Publishers of NATURE 29, Bedford Street, Strand, W.C.

Printed by R. CLAY, SONS, AND TAYLOR, at 7 and 8, Bread Street Hill, Queen Victoria Street, in the City of London, and published by MACMILLAN AND CO., at the Office, 29 and 30, Bedford Street, Covent Garden.—THURSDAY, September 25, 1879.

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE

*"To the solid ground
Of Nature trusts the mind which builds for aye."*—WORDSWORTH

No. 518, Vol. 20] THURSDAY, OCTOBER 2, 1879 [Price Sixpence

Registered as a Newspaper at the General Post Office.]

UNIVERSITY OF LONDON. B.A. AND B.Sc. EXAMINATIONS.

Sixth Edition, crown 8vo, 8*s.* 6*d.*

ELEMENTS of MECHANICS, including HYDROSTATICS. With numerous Examples. By SAMUEL NEWTH M.A., D.D., Principal of New College, London, and Fellow of University College, London. New and Enlarged Edition.

This Edition has been carefully revised throughout, and with especial reference to changes recently made in the Regulations of the University of London. [*Nearly ready.*

JOHN MURRAY, Albemarle Street.

ZOOLOGICAL SOCIETY'S PUBLICATIONS.

Now ready.

PROCEEDINGS OF THE SCIENTIFIC MEETINGS of the SOCIETY for 1879. Part III. Containing the Papers read at the Scientific Meetings in May and June, 1879. With 19 Plates, most coloured, 12*s.* With Plates, uncoloured, 3*s.*

May be obtained at the Society's Office, 11, Hanover Square, W., at Messrs. LONGMANS', Paternoster Row, E.C., or through any Bookseller.

Now ready, crown 8vo, illustrated, 6*s.* 6*d.*

PHYSIOLOGY and HYGIENE of the VOICE, with especial Reference to its Cultivation and Preservation. For the Use of Speakers and Singers. By GORDON HOLMES, Physician to the Municipal Throat and Ear Infirmary.

J. & A. CHURCHILL, New Burlington Street.

This day is published.

On the STRUCTURE and AFFINITIES of the "TABULATE CORALS" of the PALÆOZOIC PERIOD, with Critical Descriptions of Illustrative Species. By H. ALLEYNE NICHOLSON, M.D., D.Sc., &c., &c., Professor of Natural History in the University of St. Andrews. Illustrated with Engravings on Wood and 15 Lithograph Plates. Super royal 8vo, 21*s.*

WM. BLACKWOOD & SONS, Edinburgh and London.

MR. OAKLEY COLES' WORKS.

In preparation, Third Edition, demy 8vo.

DEFORMITIES OF THE MOUTH, their Mechanical Treatment. With an Appendix of Illustrative Cases. London: Churchill, New Burlington Street.

OPINIONS OF THE PRESS ON THE FIRST AND SECOND EDITIONS.

LANCET, November 28, 1868.—"The work is full of useful information . . . . . of every day utility to the practitioner."

LANCET, July 16, 1870.—'The Second Edition of this work shows that the author has continued to devote himself with zeal to the investigation and treatment of a very interesting class of cases. We recommend the work to the study of both Surgeons and Dentists."

BRITISH JOURNAL OF DENTAL SCIENCE, August, 1870.—"The Second Edition bears upon its pages the most satisfactory evidence of the industry and zeal with which he has followed up the study and practice of the specialty he has devoted himself to with so much success. . . . . . Altogether we must heartily congratulate Mr. Coles on this creditable completion of a work which cannot but redound to his credit, wherever it is known."

A MANUAL OF DENTAL MECHANICS. With 150 Illustrations. Churchill, New Burlington Street.

OPINION OF THE PRESS.

AMERICAN DENTAL REGISTER, November, 1874.—"The work we regard as a very valuable one to the student, and, indeed, for the Practitioner. It should be in every Dentist's library."

NOTES FOR DENTAL STUDENTS. 2*s.* 6*d.*
Butcher, 4, Crane-court, Fleet Street.

OPINION OF THE PRESS.

BRITISH JOURNAL OF DENTAL SCIENCE, August, 1876.—"We cordially welcome this useful little book. . . . . . Of great value to those preparing for the Dental Diploma. . . . . . We hope there will soon be a Second Edition needed."

THE DOCTOR, September, 1876.—"Carefully arranged and very complete. Indeed they seem to try to take in rather more than sufficient for Dental students. . . . . . We have no other fault to find with this note-book, which appears a model of what such a work should be."

THE MOUTH AND TEETH DURING PREGNANCY. Reprinted by permission from the Transactions of the Odontological Society. Pp. 31. Price 1*s.* 6*d.* London: Wyman and Sons, Great Queen Street.

OPINION OF THE PRESS.

THE BRITISH MEDICAL JOURNAL.—"The author has evidently paid considerable attention to the subject, and gives many useful hints as to the management and relief of the distressing toothache and neuralgia complicating pregnancy. . . . . . The remarks on treatment are practical, and will repay perusal. . . . . . The practitioner will do well to carry out the suggestions offered by the author."

FOURTH EDITION, REVISED.

Illustrated by 760 Wood Engravings and 3 Coloured Plates, and accompanied by a Series of Problems, medium 8vo, cloth, 18*s.*

DESCHANEL'S NATURAL PHILOSOPHY. An Elementary Treatise, Translated and extended by J. D. EVERETT, D.C.L., F.R.S.E., Professor of Natural Philosophy in Queen's College, Belfast.

Also, separately, in Four Parts, limp cloth. 4*s.* 6*d.* each.

Part I. MECHANICS, HYDROSTATICS, AND PNEUMATICS.
Part II. HEAT.
Part III. ELECTRICITY AND MAGNETISM.
Part IV. SOUND AND LIGHT.

"Systematically arranged, clearly written, and admirably illustrated, it forms a model work for a class in experimental physics."—*Saturday Review.*

Illustrated by Numerous Wood-cuts, fcap. 8vo, cloth, 3*s.* 6*d.*

ELEMENTARY TEXT-BOOK OF PHYSICS. By Prof. EVERETT, Translator and Editor of DESCHANEL'S "Natural Philosophy," &c.

"We have no hesitation in warmly recommending it as a good text-book for junior classes."—*Nature.*

London: BLACKIE & SON, 49 and 50, Old Bailey; and sold by all Booksellers.

On the 1st of every Month, price One Shilling.

THE ZOOLOGIST:

A MONTHLY MAGAZINE OF NATURAL HISTORY.

Third Series. Edited by J. E. HARTING, F.L.S., F.Z.S., Member of the British Ornithologists' Union; contains—

Original articles by well-known naturalists in every branch of zoology; habits of animals; arrival and departure of migratory birds; occurrence of rare birds; distribution and migration of British fresh-water fish; new or rare marine fish; local aquaria; British reptiles; British land and fresh-water mollusca, with remarks on the haunts and habits of the species; and other matters of general interest to those who delight in natural history. Reports of the Linnean, Zoological, and Entomological Societies. Reviews of natural history books. Occasional translations from foreign zoological journals of important and interesting articles in various branches of zoology. There are occasional woodcuts.
